Introduction

Large-scale assessments (LSAs) are comparative educational surveys that are widely used to inform policy and provide large datasets for educational researchers. They compare skills, knowledge, attitudes and behaviors across different populations and subpopulations of interest. The focus of these assessments is on group-level scores in contrast to large-scale testing programs that aim to report scores for individual test takers. These differences are reflected in the test and sampling design of LSAs as well as in the reporting of results. LSAs have grown and expanded over the past decades (since the late 1950s) to include a broader range of skill domains and populations, and to better meet the questions posed by policymakers and researchers worldwide (Kirsch et al., 2013). They can be

used for cross-country comparisons, school monitoring, the evaluation of growth and changes in learning progress over time (reporting of trends), and monitoring progress toward educational development goals.

Purpose and policy relevance of large-scale assessments

The overall purpose of LSA is to provide researchers and policymakers with valid data and meaningful group-level information about populations and subpopulations of interest with regard to skills, knowledge and behavior and how these relate to educational, economic and social outcomes. The focus is especially on skills that “contribute to the prosperity of nations and economies and to better lives for individuals in those nations” (Kirsch et al., 2013, p. 7). LSAs can be utilized for monitoring educational effectiveness and can help develop ways to improve the quality and equality of education worldwide.

With their rich databases, LSAs provide comparative data about countries’ student achievement in relation to key home, school, and classroom variables (Mullis and Martin, 2017). Therewith, they enable researchers to examine the relation of students’ proficiencies to their contexts for learning. They also allow for monitoring the effectiveness of a country’s educational system compared to other countries and own expectations, and for measuring progress over time (trends).

National and international large-scale assessments

LSAs can be roughly separated into national and international assessments that assess either student or adult populations of different age groups or school grades within or across countries. While student populations are assessed in classroom settings, adult populations are usually assessed in household surveys. There are also regional assessments which compare populations within a particular geographical region. In the following, examples of national and international large-scale assessments are provided.

NAEP

The National Assessment of Educational Progress (NAEP¹) conducted by the National Center for Education Statistics (NCES) was one of the first of its kind and assesses elementary and secondary grade students across the US since 1969. While a cross-country feasibility study had been conducted prior between 1959 and 1962 (see Kirsch et al., 2013), NAEP and the methods developed for it, especially at the Educational Testing Service (ETS) in the 1980s (Beaton and Barone, 2017; Kirsch et al., 2013), paved the way for other LSA that followed. NAEP assesses the core domains of reading, mathematics and science next to a number of other domains (described in the section “Content, cognition and context information” below); it is administered every 2 or 4 years depending on the subject domain, and transitioned to a digital-based administration (tablets) in 2017.

TIMSS

The Trends in International Mathematics and Science Study (TIMSS²) is conducted by the International Association for the Evaluation of Educational Achievement (IEA) and the TIMSS & PIRLS International Study Center at Boston College since 1995 and assesses students’ mathematics and science achievement. It was first implemented at grades 3 and 4, 7 and 8 and the final year of secondary school in 40 countries and since then is being implemented at grades 4 and 8 in over 60 countries. TIMSS assesses the domains mathematics and science (including problem solving related to both domains) and is administered every 4 years. It started transitioning to a digital-based assessment administration in 2019. In 1995, 2008 and 2015, the *TIMSS Advanced* study was conducted in addition to TIMSS for assessing advanced mathematics and physics achievement for students in their final year of secondary school.

PIRLS

The Progress in International Reading Literacy Study (PIRLS³) is conducted by the IEA and the TIMSS & PIRLS International Study Center since 2001; it assesses students reading achievement at grade 4 in over 60 countries. As indicated by its name, PIRLS assesses reading and is administered every 5 years. It began transitioning to a digital-based assessment administration in 2021 and implemented the additional *ePIRLS* assessment, which monitors how well students read online information.

¹<https://nces.ed.gov/nationsreportcard/>.

²<https://timssandpirls.bc.edu/timss-landing.html>.

³<https://timssandpirls.bc.edu/pirls-landing.html>.

CIVED

The Civic Education Study (CIVED⁴) was conducted by the IEA in collaboration with the Humboldt University of Berlin in two phases between 1996 and 2000. It represented the largest and most rigorous study of civic education implemented internationally up to that time. CIVED assessed 14-year-old students in 30 countries in the domains of democracy and citizenship, national identity, social cohesion and diversity, as well as the engagement in civil society. Some of the participating countries additionally conducted an optional survey of upper-secondary school students (ages 17–19).

ICILS

The International Computer and Information Literacy Study (ICILS⁵) has been conducted by the IEA since 2013 (in collaboration with the ACER in the first two cycles) and is administered in a 5-year cycle. It was designed to assess how well students in grades 8 and 9 (i.e., at the average age of 13.5 years or above) are prepared for study, work, and life in a digital world; it also measures international differences in students' computer and information literacy as well as the optional domain computational thinking. In addition to helping countries to monitor their own national targets regarding students' digital competences, ICILS provides researchers, educators, and policymakers with a data base for monitoring progress toward the UN's Sustainable Development Goals (SDGs). Furthermore, the resulting data are recognized as an official European Union (EU) target by the EU Council and Member States to support strategic priorities toward the European Education Area and beyond (2021–2030).

PISA

The Programme for the International Student Assessment (PISA⁶) is conducted by the Organization for Economic Co-operation and Development (OECD) in collaboration with the Australian Council for Educational Research (ACER) and ETS since 2000. PISA assesses 15-year-old students in over 80 countries in the core domains reading, mathematics and science, and offers an optional assessment of financial literacy since 2012. It is administered every 3 years with one of the core domains being the main domain in a particular assessment cycle. That is, new items are being developed for the main domain based on an updated framework while the other two domains are assessed with items from previous assessment cycles only (called trend items). In 2015, science was the main domain, in 2018 reading was the main domain, and in 2021 (administered in 2022 due to the covid-19 pandemic) mathematics was the main domain. Moreover, PISA offers the optional assessment of a new innovative domain in each cycle (as described in the section **“Content, cognition and context information”** below), transitioned to a fully digital-based assessment in 2015 after offering a partially digital-based administration in 2012, and started implementing multistage adaptive test designs in 2018.

PIAAC

The Programme for the International Assessment of Adult Competencies (PIAAC⁷) is a household survey conducted by the OECD in collaboration with ETS since 2012 and was preceded by the International Adult Literacy Survey (IALS) and the Adult Literacy and Life skills Survey (ALL),⁸ administered between 1994 and 1998 as well as between 2003 and 2007, respectively. PIAAC assesses 16–65-year-old examinees in some 40 countries in the domains of literacy, numeracy and problem solving in technology-rich environments. In its second cycle, PIAAC is assessing the domain adaptive problem solving. PIAAC follows approximately a 10-year cycle and was the first international large-scale assessment to offer a digital-based assessment administration for all participating countries as well as a multistage adaptive testing design (see the section **“Measurement characteristics”** below for more information on the design).

PISA for schools

The PISA-based Test for Schools (PBTS⁹) has been offered by the OECD since 2017. PBTS is based on the same framework as PISA and is assessing 15-year-old students' abilities to think critically and apply their knowledge creatively in novel contexts in the domains reading, mathematics and science. It is administered as a digital-based assessment on demand in interested schools and, to this date, available in 15 countries. PBTS aims to improving student learning opportunities and well-being by empowering teachers and school leaders through global connections and international benchmarking based on a common scale provided by PISA. By comparing their performance to international benchmarks, schools can set goals against the best school systems worldwide, better understand the challenges faced by low-performing students, and create peer-learning communities and networks with other schools and teachers.

⁹<https://www.oecd.org/pisa/pisa-for-schools/>.

These different LSAs show some variation with regard to their aims and frameworks. NAEP, TIMSS and PIRLS are more driven by countries' school curricula (Mullis and Martin, 2015, 2017; NAEP assessment frameworks¹⁰) while PISA and PIAAC are rather interested in skills needed to meet real-life challenges at home, work and in the wider community (PISA 2022 Assessment and Analytic Framework¹¹; OECD, 2021). However, the designs and methods utilized in LSAs are very similar. All LSAs are based on matrix sampling, item response theory (IRT; Lord and Novick, 1968) and conditioning or population modeling (Mislevy et al., 1992; von Davier et al., 2006; von Davier et al., 2009), and are administered in cycles to provide trend measures for evaluating changes in the performance of populations over time.

Regional large-scale assessments

This section provides examples of regional large-scale assessments which provide comparisons across different countries belonging to specific regions that share the same language and a similar culture. Like LSAs in general, regional assessments aim to provide relevant information on the status and progress of learning, monitor, evaluate, and compare the general conditions of schooling and the quality of basic education, generate information that can be used by decision-makers to formulate plans for improving the quality of education, and provide a basis for policy and practice. Because these assessments are largely implemented for low- and middle-income countries, they are also an important tool for providing data that help measure progress toward the United Nations (UN) Sustainable Development Goal 4 of the 2030 Agenda (SDG 4, ¹² Target 4.1) which proposes to “ensure inclusive and equitable quality education and promote lifelong learning opportunities for all” especially with regard to target or indicator 4.1.1 which aims to ensure that by 2030 “all girls and boys complete free, equitable and quality primary and secondary education leading to relevant and effective learning outcomes.” Note that the regional LSAs presented below are all paper-based assessments.

PASEC

The Programme for the Analysis of Education Systems (PASEC¹³; Programme d'Analyse des Systemes Educatifs) has been conducted by the Conference of Ministers of Education of French-Speaking Countries (CONFEMEN) since 1993. It started as a diagnostic tool to assess the progress of students from the beginning to the end of the same school year in grades 2 and 5 in countries of Sub-Saharan Africa, the Indian Ocean, the Middle East and South-East Asia, but has evolved since 2012. PASEC's new focus is on the comparison of national assessments in francophone Sub-Saharan countries for enabling a better understanding of the effectiveness and equity of education systems, in line with other international programs such as PISA, PIRLS or TIMSS. Since then, PASEC has been administered in 13 countries in Francophone West Africa to assess students' achievement in mathematics and reading French (including listening comprehension) at grades 2 and 6 (i.e., at the beginning and end of primary school). Results are available for the 2014 and 2019 assessment cycles and more cycles will follow.

ERCE

The Regional Comparative and Explanatory Study (ERCE¹⁴) is conducted by the Latin American Laboratory for Evaluation of the Quality of Education (LLECE) of the United Nations Educational, Scientific and Cultural Organization (UNESCO) since 1997. It assesses students at grades 3 and 6 in Latin America and the Caribbean in the domains of reading, writing, mathematics, and science, and is an important tool for monitoring the SDG 4. ERCE was last implemented in 18 countries in 2019.

SACMEQ

The Southern and Eastern African Consortium for Monitoring Educational Quality (SACMEQ¹⁵) has conducted cross-national assessments in 15 anglophone countries in the Southern and Eastern Africa region since 1995. To date, three cross-national educational research projects have been implemented to assess achievements in reading English and mathematics at grade 6: SACMEQ I (1995–1999), SACMEQ II (1998–2004) and SACMEQ III (2005–2010). While SACMEQ I assessed only students' achievement (reading), SACMEQ II and III assess students' achievement as well as the performance level of teachers (reading and mathematics). Moreover, SACMEQ II and III included linking items from TIMSS and PIRLS with the goal of enabling comparisons between these regional and international assessments (Cresswell et al., 2015).

SEA-PLM

The Southeast Asia Primary Learning Metrics (SEA-PLM¹⁶) was initiated by the Southeast Asian Ministers of Education Association (SEAMEO) and UNICEF in 2012 with the aim to realize the SDG 4 and to further improve the quality of primary education in Southeast Asia. SEA-PLM assess and monitors students' achievement in mathematics, reading, writing, and global citizenship at primary grade 5. It is based on the SEAMEO political framework and is embedded within national education systems in order to be considerate of the regional context and values. The assessment was first implemented in 6 countries in 2019, in collaboration with ACER.

PILNA

The Pacific Island Literacy and Numeracy Assessment (PILNA¹⁷) is administered by the Educational Quality and Assessment Division (EQAP) of the Pacific Community in collaboration with the Pacific Ministers for Education and ACER, and has received financial support from the Australian Department of foreign Affairs and Trade as well as from the New Zealand Aid Programme. It has been implemented in 3-year cycles since 2012, and was administered to 15 Pacific countries in 2018. PILNA was developed from the component skills in literacy and numeracy common to all Pacific countries, and assess students' basic numeracy and literacy skills after completing four and 6 years of primary education.

Comparing regional and international large-scale assessments for building capabilities in low- and middle-income countries

This section describes studies that aim to build capabilities in low- and middle-income countries by either providing assessments as a preliminary step toward the participation in international large-scale assessments (PISA for Development and IEA's LaNA), by establishing a comparison between regional and international large-scale assessments for countries that are not yet ready to participate (IEA's Rosetta Stone), or both (IEA's LaNA). The main goal is to provide countries with data and international comparisons that help improve their education systems (students' learning, teachers' education, school systems' efficacy) so that students can meet minimum proficiency standards in reading and mathematics, as defined in the UN's SDG 4. For more than half of the world's children this has not been the case, even before the COVID pandemic, and with school closures during the pandemic impacting about 90% of students worldwide, it is more important than ever to concentrate on improving global education. Moreover, participation in such studies provides educational officials, researchers and analysts with training in implementing standardized LSA procedures, assessment administration, and analyzing the data and reporting the outcomes in preparation for participation in international large-scale assessments such as TIMSS, PIRLS or PISA in the future.

PISA-D

The PISA for Development programme (PISA-D¹⁸) was designed as a 6-year project and conducted by the OECD between 2014 and 2019 through a partnership involving eight low-income countries, concerned development partners (DAC members plus the World Bank, UNESCO, UNICEF and other UN bodies and regional organizations), ETS and The Learning Bar. It aimed to encourage and facilitate the participation of interested low- and middle-income countries in PISA by providing instruments that are more relevant for the contexts found in such countries but which produce scores that are on the same scales as the main PISA assessment. PISA-D assessed students in the domains of reading, mathematics, and science, and was administered as a paper-based assessment to in school student populations. It was also administered to out-of-school children as a digital-based household survey (tablets) following the PIAAC model. The goal was to provide policy makers with insights on how to improve their educational systems, help build the capacity of participating countries to conduct LSA and make use of resulting data, and contribute to monitoring progress toward nationally-set targets for improvement as well as toward the SDG 4. Since 2021, PISA-D was integrated into the main PISA test, making the assessment more accessible and relevant to middle- and low-income countries.

IEA's Rosetta Stone

Named after the famous archeological discovery that enabled translation between different written languages, the Rosetta Stone¹⁹ study, conducted by IEA and the TIMSS & PIRLS International Study Center, enables relating children's achievement on countries' regional and national assessments to achievement at the TIMSS and PIRLS international benchmarks. Therewith, IEA's Rosetta Stone study allows countries to compare their students' achievement internationally and provides data that help countries measure global progress toward the SDG 4²⁰. Administering the paper-based Rosetta Stone linking booklets containing TIMSS and PIRLS items

¹⁶<https://www.seaplm.org>.

¹⁷<https://eqap.spc.int/PILNA>.

¹⁸<https://www.oecd.org/pisa/pisa-for-development/>.

¹⁹<https://www.iea.nl/studies/additionalstudies/rosetta>.

²⁰Please refer to the following document: <http://unesdoc.unesco.org/images/0026/002606/260607E.pdf>.

together with the national or regional assessments provides data for the TIMSS & PIRLS International Study Center to establish concordance tables that relate countries' achievement on their national or regional assessment to the TIMSS and PIRLS International Benchmarks. Countries who participate in the Rosetta Stone study are provided with information about the proportions of primary school students reaching the TIMSS and PIRLS achievement benchmarks. In 2022, the first concordance tables for reading and mathematics were constructed for the regional assessments PASEC and ERCE.

IEA's LaNA

The Literacy and Numeracy Assessment (LaNA²¹) was developed by the TIMSS & PIRLS International Study Center upon request by the IEA, with the final instrument being established in 2021 after a multi-country pilot, including student samples from Africa, Asia, the Caribbean, and Europe. LaNA is aimed at measuring basic literacy and numeracy skills at the end of primary school, and targets student populations for which TIMSS and PIRLS are too challenging. LaNA is a shorter, less demanding paper-based assessment and can be used to identify strengths and weaknesses in education systems and as a precursor to implementing TIMSS or PIRLS. LaNA also aims to establish a linkage between its literacy and numeracy achievement scales and the TIMSS and PIRLS reading and mathematics scales. To accomplish this, LaNA uses additional paper-based linking booklets containing material sourced from applicable (easier) parts of the original TIMSS and PIRLS assessments. Countries administering LaNA will be able to use their students' performance on LaNA to estimate how they would perform against the lower TIMSS and PIRLS achievement benchmarks which can serve as measures for SDG 4. In contrast to IEA's Rosetta Stone, where the constructs measured by regional assessments differ from the constructs measured in TIMSS and PIRLS (yet, are similar enough to establish a concordance), the constructs measured with LaNA are actually based on the comprehensive TIMSS and PIRLS frameworks.

Content, cognition and context information

The constructs measured by LSAs are based on comprehensive conceptual assessment frameworks which provide definitions and examples for each measure, and the background for why these are important for everyday life, work, school or economy. These frameworks are established by content experts from different fields such as education, psychology, sociology and measurement. In addition to what an assessment intends to measure, conceptual assessment frameworks provide information on how the assessment should be structured. According to [Mislevy and Riconscente \(2005\)](#) the conceptual assessment framework includes the student or proficiency model, the evidence model, the task model and the assembly model. The student model describes what is being measured and defines one or more variables that are related to the construct(s) of interest (knowledge, skills, abilities). The evidence model defines how the responses of examinees to tasks should be scored (evaluation component) and how these scores are related to the measurement (measurement model). The task model describes how items need to be developed and structured to obtain the behavior or responses needed for the evidence model (e.g., remembering versus recognizing or problem solving), including item forms (e.g., multiple-choice or constructed response items), and the materials used (including directives, manipulatives, and features). The assembly model relates the student, evidence and task model to one another, and represents the accuracy, breadth and diversity of the domain being assessed (e.g., selecting a given items from particular subdomains, and whether to present them in a linear or adaptive test administration).

The purpose of assessment frameworks is not only to guide the development of the assessment, but also to guide the reporting of results and provide a common language and accountability for stakeholders. To ensure the relevance of the measured constructs in an ever-changing world, assessment frameworks are constantly being updated for each assessment cycle. To ensure construct validity, the item development based on these frameworks passes through multiple development, review and revision stages overseen by different (often international) experts, including translation and verification processes, and actively involves participating countries to ensure that the content and difficulty levels are suitable for most students in each country.

Core domains

The core achievement domains in most LSA are reading and literacy, mathematics and numeracy, and science. Each domain consists of a content dimension, specifying the subject matter to be assessed, and a cognitive dimension, specifying the thinking processes to be assessed. Hence, each achievement domain consists of different subdomains.

Example, PIRLS 2021 reading

The domain reading in PIRLS is defined as "... the ability to understand and use those written language forms required by society and/or valued by the individual. Readers can construct meaning from texts in a variety of forms. They read to learn, to participate in communities of readers in school and everyday life, and for enjoyment." ([Mullis and Martin, 2019](#)). This definition comprises online reading skills as well, and focusses on the following subdomains:

²¹<https://www.iea.nl/studies/iea/LaNA>.

- Purposes for reading
 - Literacy experience
 - Acquire and use information
- Processes of comprehension
 - Focus on and retrieve explicitly stated information
 - Make straightforward inferences
 - Interpret and integrate ideas and information
 - Evaluate and critique content and textual elements

Example, PISA 2018 reading

The domain reading in PISA 2018, where reading was the main domain, is defined as “understanding, using, evaluating, reflecting on and engaging with texts in order to achieve one’s goals, to develop one’s knowledge and potential and to participate in society” (OECD, 2019) and comprises the following subscales:

- Text formats
 - Continuous texts (newspaper reports, essays, novels, short stories, reviews and letters)
 - Non-continuous texts (lists, tables, graphs, diagrams, advertisements, schedules, catalogs, indexes and forms)
 - Mixed texts (a combination of continuous and non-continuous texts)
- Text sources (units of texts)
 - Single source texts
 - Multiple source texts
- Cognitive processes
 - Locate information
 - Understand
 - Evaluate and reflect

The definitions and subdomains of reading in PIRLS and PISA show some similarities and overlap, but also a number of differences. Moreover, the goals of these LSAs have subtle but important distinctions. Similar to NAEP, which focuses on the US school system, as opposed to cross-country comparisons, PIRLS aims to measure school-based curricular attainment while PISA is a literacy-based assessment that focuses on the “yield” of education systems and the application of skills in real-world contexts (Stephens and Coleman, 2007). Hence, constructs across different LSAs cannot be compared directly.

International reporting and comparisons usually focus on results in the overall domain (e.g., reading), but information at the subdomain level (e.g., locate, understand, and evaluate information) is available in the database as well for further analysis at the national level (note that subdomains are generally highly correlated).

Additional and innovative domains

Next to these core achievement domains, different LSAs typically assess additional domains of interest. NAEP, for example, provides measures for arts, civics, economics, geography, US history, technology and engineering, and writing. The transition of LSAs to a computer-based administration also offers the assessment of new and innovative domains through interactive item types and new materials and environments. TIMSS, PISA and PIAAC provide different types of problem-solving measures, for example. TIMSS assesses problem solving and inquiry as part of mathematics and science; PIAAC assessed problem solving in technology rich environments in cycle 1 and will assess adaptive problem solving in cycle 2. PISA assessed collaborative problem solving in 2015. PIRLS, PISA and PIAAC also measure digital reading, and PISA offers the measurement of financial literacy (which is not specific to computer-based administration) as well as the option of a new innovative domain in each cycle, which is only assessed once, such as collaborative problem solving (2015), global competence (2018), creative thinking (2021); (due to the COVID pandemic administered in 2022), or learning in the digital world (2025). ICILS offers the option of assessing computational thinking (including programming as well as structuring and manipulating data), in addition to its core assessment of computer and information literacy skills.

Context variables

In addition to collecting achievement data, LSAs collect a large set of policy relevant background or context variables through student, parent, and school questionnaires as well, which are based on self-ratings. These include student attributes, home and school contexts for teaching and learning, students’ home background, school and classroom resources, teacher and teaching quality, and equity. In addition to demographic information, background questionnaires provide valuable information on the learning climate within a school, students socioeconomic background and motivation for learning, and they can help to measure a wider range of 21st century skills. Similar to achievement domains, the development and structure of background questionnaires is based on comprehensive assessment frameworks, and their content is updated with every assessment cycle to reflect new topics of

emerging relevance in addition to topics of ongoing importance across cycles. Context variables can be used to examine and understand group differences in cognitive proficiencies, can be related to other external variables like socioeconomic status, school, teaching or economic systems, and have the potential to be leveraged to maximize educational outcomes (Lee and Chen, 2019; Lee and Stankov, 2018).

Measurement characteristics

Abilities, skills, or proficiencies measured by LSAs are not directly observable but constitute hidden or latent traits. They can be modeled based on the evidence collected through examinees' responses to assessment items (i.e., observable behavior) using measurement models such as IRT and conditioning or population models. These models are used to construct unidimensional (if possible) and comparable scales for each construct of interest by estimating common item parameters (cf. Khorramdel et al., 2020a,b,c; Yamamoto et al., 2013a, updated 2019). Establishing comparable achievement and contextual scales across populations within countries, across countries, and across assessment cycles is an important goal of international large-scale assessments and the basis for group comparisons and the reporting of trend (cf. Khorramdel et al., 2020a,b). Consequently, measurement invariance of item parameters and scales has to be achieved to ensure that results can be interpreted similarly across different groups of interest. Conceptually, measurement invariance is concerned with minimizing construct irrelevant sources of variance in item responses so that the relationship between items and the latent trait measured by those items (represented by test scores) is not affected by group membership (Mellenbergh, 1989). Measurement invariance in LSA is achieved through high standards in instrument development, translation and adaptation, specific sampling and test design considerations, standardized data collection, the use of IRT and conditioning models in data analysis, and rigorous quality evaluation on each step of the way. Each LSA cycle is preceded by a field test for evaluating the quality of the instruments, procedures and building capabilities (i.e., preparing countries for the main assessment).

General design considerations

The design of a LSA has to fulfill multiple goals to establish reliable, accurate, comparable, meaningful, and policy relevant results. It has to ensure comprehensive construct coverage for all groups of interest, comprehensive coverage of the target population(s), and comprehensive reporting coverage at the population and subpopulation level. The design has to account for a wide range of student achievement, allow for the measurement of trends and, at the same time, incorporate innovations (regarding constructs and test development, test administration, methods and analysis) (cf. Kirsch et al., 2020).

LSA designs are based on two important sampling considerations, taking advantage of the fact that group and subgroup comparisons are of interest as opposed to comparing individual test-takers: population sampling and domain sampling (Beaton and Barone, 2017).

Population sampling

Population sampling refers to the selection of samples with the aim to provide reliable and accurate measures at the population and subpopulation level. The sample has to be large enough to provide estimates with sufficiently small standard errors, yet small enough to be cost effective. Hence, the goal is to select the smallest sample size that will meet the defined measurement standards (Beaton and Barone, 2017). Moreover, the drawn samples need to be equivalent and representative, and have a similar distribution of characteristics like in the defined target population. To achieve this, sampling designs make use of methods like randomization, stratification and multistage-sampling (e.g., LaRoche et al., 2020). The way in which results have to be reported (e.g., for which subpopulations results are required) is another important variable that influences the sample size and the sampling design.

Domain sampling

Domain sampling determines the breadth of the measurement within a subject area and refers to the achievement of a valid representation of frameworks and constructs (domains and subdomains) and reliable construct measures. For this purpose, a large number of items is required for each assessed domain, more items than can be possibly taken by one test-taker. Moreover, assessing multiple domains will increase the number of items further. Therefore, LSAs make use of matrix sampling and balanced incomplete block (BIB) designs, which includes multiple test forms with a rotated block design (Messick et al., 1983; von Davier et al., 2006; von Davier and Sinharay, 2013).

Matrix sampling

Matrix sampling and BIB designs allow the administration of a large number of items to achieve broad construct coverage and ensure that the complete item pool is administered to the population of interest while keeping the individual student burden (i.e., time spend on the assessment) as low as possible. More precisely, each student usually responds to one test booklet that comprises only a subset of the available items. These test booklets are linked through common item sets (blocks) ensuring that a common scale can be constructed even though students respond to different sets of items. Moreover, the position of items across test booklets is varied (rotated) to balance out possible position or order effects. Because matrix sampling allows for the incorporation of a large item pool in the design, trend items from prior assessment cycles can be administered together with new items to account for construct updates and innovations. Based on this linking across different cycles, matrix sampling allows for the reporting

of trends and changes in achievement over time. It should be noted that matrix sampling does not provide reliable achievement estimates at the individual student level, but allows for reliable estimates at the group and country level. Matrix sampling reduces the time and costs for participating countries, immensely, compared to census testing where all individuals of a population of interest are sampled.

Adaptive testing

One important challenge faced by international LSAs, in particular, is the variability of proficiencies across and even within countries, as examinees with a broad range of proficiency levels, school curricula and sometimes age (e.g., in PIAAC) are tested in multiple languages often associated with diverse cultural backgrounds. For example, in lower performing countries students might struggle to answer items while for students in higher performing countries these items might not be challenging enough. With more and more countries participating in international LSAs, this is an increasing concern. For example, 32 countries participated in PISA in 2000 while 90 countries participated in 2021/2022. Hence, LSA test designs benefit from some form of adaptiveness to better match item difficulty with examinee ability (cf. [Martin et al., 2019](#); [Kirsch et al., 2020](#); [Yamamoto et al., 2018b](#)). Adaptive test designs can increase test efficiency and the accuracy of LSAs by providing better coverage for a diverse range of ability distributions in addition to increasing student motivation and decreasing item-level nonresponse (omitted and not reached items) ([Yamamoto et al., 2018a,b](#)).

Group adaptive designs

This type of design applies adaptive testing at the country level without the need for individual routing of students. Item difficulty and average country proficiency are estimated based on prior assessment cycles and/or the field test. Based on this information, items can be labeled as difficult, medium and easy, for example, and combined into booklets or forms with different difficulty levels. PISA used such a design in its 2015 cycle and similar ones in prior cycles. Countries could choose between standard forms or easier forms, where two of the standard item sets were replaced by easier item sets in approximately one-third of the forms ([OECD, 2017](#)). Until 2015, PISA also offered a special 1 h assessment instrument (Une Heure or UH) for students with special educational needs containing about half as many items as the other PISA instruments. PIRLS 2021 and TIMSS 2023 use a more advanced design where all booklets are differentiated into either less difficult or more difficult booklets ([Martin et al., 2019](#); [Yin and Foy, 2021](#)). All booklets are administered in all countries, but the distribution of booklets depends on a countries' average proficiency.

Multistage adaptive designs

A computer-based test administration of LSAs allows for the implementation of more advanced adaptive test designs, such as multistage testing (MST) with a higher level of adaptiveness. That is, the administration of item sets with different difficulty levels depends on the student's proficiencies in prior item sets and follows a routing system. PIAAC was the first international LSA implementation of an MST design, in 2012. The PIAAC MST design in the first cycle was based on information from both the background questionnaire and the cognitive assessment, and had two levels of adaptation ([Kirsch et al., 2020](#); [Yamamoto et al., 2018a](#)): (1) based on their computer skills and experience, examinees were routed to either a paper- or a computer-based assessment and (2) within the computer-based assessment, examinees' proficiency levels were determined based on responses to prior cognitive items as well as information about their educational level and native language, and then used to assign examinees to the different adaptive stages. A probability-based multistage adaptive algorithm was used to control the item exposure rate for enabling broad construct coverage and for minimizing differential item functioning (DIF). The second cycle of PIAAC will be digital-based only (using tablets) and will use an adjusted MST design. PISA was the second international LSA to implement an MST design for its reading domain in 2018. The PISA MST design can be viewed as a three-stage (core, stage 1, and stage 2), two-level (difficult and easy item blocks²²) design ([OECD, 2020](#); [Yamamoto et al., 2019](#)) where students are routed to either more difficult or easier item blocks, first in stage 1 and then in stage 2, based on their performance in the previous core stage. The assignment in stage 2 is based on the combined performance of students in the core stage and stage 1. The PISA design also accounts for possible item position effects by reversing stage 1 and 2. Both, PIAAC and PISA MST designs use an additional probability layer matrix to control for item exposure to ensure a more accurate item parameter estimation and sufficient construct coverage at the population level.

Establishing comparable scales and plausible values

Given the complexities of the data collection and the need to describe student achievement on a scale that is comparable across samples and that represents the entirety of the assessment frameworks, LSAs utilize IRT models ([Lord and Novick, 1968](#)) to provide accurate measures of student proficiency distributions. IRT models have important advantages compared to classical methods in that they directly support the creation of comparable scales across multiple forms of a test, regardless of which student took which items. IRT has become one of the most important tools of educational measurement as it provides a flexible framework for estimating proficiency scores that allows establishing scales with a common meaning over different sets of items measuring the

²²In the PISA MST design, each item block comprises multiple item sets and each item set comprises multiple items.

same construct, different populations, and different time periods., which is especially useful in international large-scale assessments (von Davier et al., 2019b).

Based on the estimates from the IRT model and the available context variables from background questionnaires (usually the student questionnaire), a conditioning or population model is estimated. This approach can be viewed as an imputation model for the unobserved proficiency distribution that aims at obtaining unbiased group-level proficiency distributions by utilizing information about the extent to which background or context variables are related to the proficiency variable (von Davier et al., 2006, 2009; von Davier and Sinharay, 2013). The goal of population modeling is to produce posterior distributions of proficiencies from which plausible values (PVs) can be drawn. PVs are the basis for all reporting of proficiency data in LSAs, allowing reliable group level comparisons and the reporting of trend. Since PVs are group-level estimates, they cannot be used or interpreted like individual test scores.

The use of IRT and population models in the context of LSAs such as PIAAC, PISA, and TIMSS, and the proper use and interpretation of PVs, are illustrated by Khorramdel et al. (2020c), von Davier (2020), Yamamoto et al. (2013a,b) or in the PISA 2018 technical report (OECD, 2020). See also Jewsbury (2023), for more information on this subject.

Trends and innovations

Providing trends over time in an everchanging world is one of the biggest challenges of LSAs. In the same way that the world and skills around us change—what and how we learn (e.g., on computers, tablets, or smartphones), and the skills we need to participate successfully in school, in the workplace and in our everyday lives (e.g., technology related skills or digital reading)—LSAs strive to evolve and improve with each assessment cycle. However, the reporting of trends is based on comparable scales over time; significant changes from one assessment cycle to the next can potentially break the trend. Therefore, changes in content or methods have to be made gradually to ensure that trends can be measured while, at the same time, moving into the future.

One of the most important recent changes in LSAs was the transition from a paper-based to a digital-based administration (DBA). PIAAC has used a DBA since 2012, PISA moved to a DBA in 2015 for the majority of countries, TIMSS did so in 2019, followed by PIRLS in 2021, and NAEP in 2022. DBA enabled the implementation of a number of innovations that enhance LSA in different ways. DBA can make the assessment potentially more engaging and provide enhanced accommodations for students with special educational needs. Furthermore, it introduces higher standardization for test administration and test security, the possibility to measure existing domains in new ways and new domains through innovative and interactive tasks (e.g., experiments and simulations), new item types and tools (e.g., highlighting text, drop down, calculator, drawing), and the collection log and process data (such as response time, types of actions and action sequences, mouse movements, different nonresponse types).

These new data types can be used to evaluate the quality and validity of LSA data (Yamamoto and Lennon, 2018), and to advance methods for analyzing LSA data and, therewith, the accuracy and fairness of test scores (von Davier et al., 2019a). Process data can also potentially deepen our understanding of what students know and how they approach problem solving tasks (Mullis et al., 2021), as well as how they engage with cognitive and noncognitive assessment content, by examining behaviors such as guessing behavior and test-taking effort (Pokropek, 2016; Pokropek et al., 2022; Ulitzsch et al., 2020a, 2021), revisit behavior (Bezirhan et al., 2021), nonresponse behavior (Pohl et al., 2019; Ulitzsch et al., 2020b) and navigation patterns (He and von Davier, 2015; He et al., 2021).

Another innovation introduced by DBA is the use of automated scoring of text and image responses to reduce the workload of human raters and related costs, and to improve scoring reliability (Sukkarieh et al., 2012; von Davier et al., 2022; Yamamoto et al., 2017; Zehner et al., 2016). Furthermore, DBA allows for the implementation of MST designs for more accurate measurement at lower and higher proficiency levels, and to accommodate the participation of countries with a larger variation in average student proficiency (Yamamoto et al., 2018a,b, 2019).

The expansion of LSA to include a wide range of participating countries and populations within those countries, as well as to assess constructs beyond typical academic domains of reading, mathematics and science reflect the “growing recognition of the need for lifelong learning as a tool to succeed in rapidly changing economies” (Kirsch et al., 2013, p. 14). However, every change needs to be supported by extensive research and scientific studies before they are operationally implemented in LSA, especially with regard to possible impacts on the measurement of trends. The transition to DBA, for example, required the study of potential mode effects, and the IRT scaling methods needed to be extended to treat such effects in cases where they occur (Fishbein et al., 2018; von Davier et al., 2019a). Similarly, the implementation of MST in PISA was preceded by a study on item position effects (Yamamoto et al., 2018b) and simulation studies that compared the efficacy of different MST designs (Yamamoto et al., 2019).

Reporting of results

Results of LSAs are reported at the international and at the national level. At the international level, the international databases, technical documentation (including information on instrument development, sampling and test design, as well as methods and procedures), and policy related reports (including cross-country comparisons) are available on the websites of the organizations that conduct these LSAs (e.g., NCES, IEA, TIMSS & PIRLS International Study Center, OECD). At the national level, each country

produces detailed reports based on their own country-level results, including the comparison of subgroups and samples within countries and descriptions of educational systems.

To provide meaningful interpretation, results are usually reported with regard to different benchmarks or proficiency levels that describe what students or examinees at each level typically know and can do. TIMSS and PIRLS, for example, provide regular reports of the percentages of students reaching advanced, high, intermediate, and low international benchmarks of achievement in reading and mathematics, which can also be used as minimal proficiency standards according to SDG 4.²³ PIAAC and PISA report results at different proficiency levels, usually 5 to 6 levels respectively. Each benchmark or proficiency level is defined by certain score ranges and cut-points. Examinees whose proficiency estimate places them at a certain point on a proficiency scale would be more likely to successfully complete items at or below that point.

Full transparency of the data and results are instrumental in the impact of LSAs on educational policies and their use in educational research. Following the publication of these reports and databases, researchers engage in secondary analysis that can provide additional information and insight, for example, by explaining reasons for group differences or education inequality. It is important to stress again, that LSA results are not meant to be interpreted or used at the individual student or examinee level, nor as school rankings; they are designed to provide group-level results only and aim to support improvement efforts for whole educational systems or defined subgroups such as school types or certain student subgroups (e.g., gender) given that the sample size allows for it based on the sampling design. von Davier et al., 2019b

Conclusion

There is an increasing need to evaluate the effectiveness of school systems and to improve education given that we live in a more and more technology driven world with growing complexity, global challenges and educational inequity. This is not only true for young students but also for adult populations, especially given the recent focus on lifelong learning and the need to upskill and reskill young and prime working age adults. This educational challenge is reflected in the growing importance of LSAs at the national, regional and international level. To balance the need for both the reporting of trends (look to the past) and the implementation of innovations (look to the future), LSA are constantly striving to advance. They do so by (1) continuously extending the comprehensive frameworks to measure cognitive proficiencies and noncognitive variables and to include 21st century skills that are relevant for success in school, work and everyday life, and (2) by advancing the methods and procedures for establishing higher measurement accuracy and validity, and more inclusiveness for a larger variety of countries and economies. LSAs, now more than ever, can influence the development of skills that are needed to successfully navigate through our fast-changing world and adapt to it. To provide relevant information to policy makers means to identify mechanisms of change and the related personal characteristics and skills, to develop appropriate measures of these skills and to deliver learning opportunities to those who need them.

Introduction and design

Large-scale educational surveys (LSES) are designed to measure what individuals know and can do within a variety of subject domains. Examples include the National Assessment of Educational Progress (NAEP) and the National Adult Literacy Survey (NALS) in the United States; the National Educational Panel Study (NEPS) in Germany; and the Program for International Student Assessment (PISA), the International Assessment of Adult Competencies (PIAAC), the Trends in International Mathematics and Science Study (TIMSS), and the Progress in International Reading Literacy Study (PIRLS) internationally. LSES typically have at least five major features in common that motivate commonalities in their methodological foundations:

Focus on group-level inference

Perhaps the most defining feature of LSES is the focus on group-level inference. Unlike other education assessments that may provide scores to individual test takers to inform high-stakes decisions such as student placement, LSES do not provide scores to individual test takers and in fact may be prevented by legislation from reporting on individual test results. Instead, LSES report on summaries of the ability distribution within groups of interest, such as the mean of ability for male students, the difference in means of ability for students with low and high socioeconomic status, and the proportion of students above a threshold of ability known as an achievement level.

Matrix sampling design

The desire to have a large pool of items in the assessment to satisfy content and validity requirements in LSES conflicts with the desire to minimize test taker burden from lengthy tests. Longer testing times may be associated with fatigue, reduced motivation, reduced participation, and disruption, particularly because LSES do not provide individual scores. To relieve this conflict, test takers receive only a sample of items from a larger item pool, known as matrix sampling. Matrix sampling in LSES is typically implemented using a balanced incomplete block (BIB) design (Messick et al., 1983). In a BIB design, items in the item pool are allocated to mutually exclusive item blocks. Test takers receive two or more item blocks in a design that ensures all blocks are observed an equal number of times in each position and all possible block pairings are observed.

Multistage sampling design

For logistical and cost reasons, LSES typically use a multistage probability sampling design. For example, NAEP samples students within schools, schools within primary sampling units, and primary sampling units within the population (Rust and Johnson, 1992; Rust, 2013).

Emphasis on trend reporting

Typically, LSES are regularly re-assessed, with a duration between surveys as short as two years (in the case of NAEP reading and mathematics at grades 4 and 8) and as long as ten years (in the case of PIAAC). While the regular assessments are rarely identical in terms of assessment design, item pool, and administration, changes to the surveys are typically minimized to reduce potential confounds on comparisons across results from surveys administered at different times (Zwick, 1992).

Collection of contextual information

In addition to the cognitive assessment of what the test taker knows and can do, LSES collect contextual information about the test taker. The contextual information may be collected from existing databases or may be collected with questionnaires provided to the test taker during the administration of the LSES. The contextual information is typically used to contextualize differences in performance and to define the groups for group-level inference but may also be used as an independent source of data separate from the cognitive assessment (Bertling et al., 2016b).

In this chapter, we first detail the core analysis methodology common to most LSES that was motivated to handle the major features detailed above. Next, we review recent research on extensions and advancements to the core analysis methodology.

Core analysis methodology

Item response theory

The design of LSES to efficiently collect information most useful for policymakers and other stakeholders introduces several technical challenges in the analysis. As test takers only receive a subset of the entire assessment under the matrix sampling design, the assessment form each test taker receives may differ in terms of content, subscale or subject domain distribution, as well as assessment difficulty. These differences in the psychometric properties of the assessments preclude the applicability of some conventional methods of aggregating the data.

In education assessment and research, best practice to estimate scores while accounting for differences in the assessment design is considered to be latent trait models (Embretson and Reise, 2000; van der Linden, 2016). LSES typically use latent trait models within the framework of item response theory (IRT), a model that is suited for the item types used in LSES (see Ackerman, this volume, and Cai, this volume, for unidimensional and multidimensional item response theory, respectively).

With IRT, different item types may be modeled with different item response functions, which describe the dependency of item responses on the latent ability of the test taker. For example, the two-parameter logistic model (2PL; Birnbaum, 1968) is commonly used for dichotomously-scored items where the correct answer cannot be selected randomly,

$$P(Y_j = 1 | \theta_i, \beta_j) = \text{logistic}(a_j(\theta_i - b_j))$$

where Y_j is the response variable for item j scored as 1 (correct) or 0 (incorrect), θ_i is the latent ability for test taker i , $\beta_j = \{a_j, b_j\}$ is the item parameters for item j , a_j is the discrimination for item j , b_j is the difficulty of item j , $P(\cdot | \cdot)$ is a conditional probability and $\text{logistic}()$ is the standard logistic function.

For other item types, other models may be used. For example, NAEP uses the three-parameter logistic model (3PL; Birnbaum, 1968) for multiple choice items and the generalized partial credit model (GPCM; Muraki, 1992) for polytomous items. Also, latent ability may be multidimensional, as in the case of a survey with multiple subscales. In this chapter, latent ability is treated as unidimensional for simplicity, but the equations may be readily generalized for the multidimensional case.

To model the pattern of item responses on the assessment, the item responses are assumed to be independent to each other conditional on latent ability (locally independent), that is,

$$P(Y = y_i | \theta_i, \beta) = \prod_{j=1}^J P(Y_j = y_{ij} | \theta_i, \beta_j)$$

where $Y = \{Y_j\}_{j=1}^J$, $y_i = \{y_{ij}\}_{j=1}^J$, y_{ij} is the response for test taker i on item j , $\beta = \{\beta_j\}_{j=1}^J$, and J is the total number of items.

When IRT is used to analyze LSES data, the matrix sampling design may be conceptualized as a missing data problem: most item responses for each test taker are missing, as most items are not presented to each test taker. The assignment of assessment forms to each test taker is carefully randomized to ensure this missing data can be classified as Missing Completely at Random (MCAR; Rubin, 1976; see Johnson, 1992).

LSES typically use marginal maximum likelihood (MML) estimation via an expectation-maximization (EM) algorithm (Bock and Aitkin, 1981; Dempster et al., 1977). In MML, items that were not presented to a test taker are ignored in that test taker's likelihood calculation (Rubin, 1976). Specifically, the following likelihood is maximized to estimate the parameters of the IRT model:

$$L(\beta, \mu, \sigma^2 | y) = \prod_{i=1}^N w_i \int \prod_{j \in s_i} P(Y_j = y_{ij} | \theta_i, \beta_j) f(\theta_i | \mu, \sigma^2) d\theta_i$$

where $L(\cdot | \cdot)$ is a likelihood, μ is the mean of the latent variable, σ^2 is the variance of the latent variable, $y = \{y_i\}_{i=1}^N$, N is the total number of test takers, w_i is the sampling weight for test taker i , and s_i is the set of items that test taker i received.

MML estimation is consistent provided that any ignored missing data is Missing at Random (MAR; Rubin, 1976). MCAR missing data, such as that resulting from matrix sampling, is MAR. Furthermore, provided that the IRT model is specified appropriately, missing data due to an adaptive or targeted testing design is also MAR (e.g., Eggen and Verhelst, 2011; Jewsbury and van Rijn, 2020, 2021), as well as missing data due to time limits (Mislevy, 2016).

IRT-latent regression

While IRT enables the analysis of LSES data on a common ability metric, the core technical challenge is the estimation of the distribution of ability for each group of interest. With this aim, LSES use IRT-latent regression models (IRT-LRM; Mislevy, 1984, 1985). IRT-latent regression models can be estimated by maximizing the following marginal likelihood,

$$L(\Gamma, \sigma^2 | x, y, \beta) = \prod_{i=1}^N w_i \int \prod_{j \in s_i} P(Y_j = y_{ij} | \theta_i, \beta_j) f(\theta_i | \Gamma, \sigma^2, x_i) d\theta_i$$

where $x = \{x_i\}_{i=1}^N$, x_i is the vector of contextual information for test taker i , Γ is the vector of regression coefficients, σ^2 is the residual variance, and $f(\cdot | \cdot)$ is a density. Usually, θ_i conditional on x_i is assumed to be normally distributed, with a mean of $\Gamma'x_i$ and a variance of σ^2 .

The parameters are typically estimated via an EM algorithm (Dempster et al., 1977; Mislevy, 1984, 1985). The E-step is often performed with either numerical integration or Laplace approximation (Thomas, 1993), depending on the dimensionality of ability. The item parameters are estimated prior to the IRT-latent regression, and the estimates of the item parameters are treated as the known values of β when estimating the latent regression parameters $\{\Gamma, \sigma^2\}$ (see Thomas and Gan, 1997).

Based on the IRT-latent regression, estimators for group-level parameters of interest may be defined for any group g , where a dummy coded variable indicating membership in group g is included in x . For example, the estimator for the mean of ability in group g is

$$\hat{\mu}_g = \hat{\Gamma}' \bar{x}_g$$

where $\hat{\Gamma}$ is the maximum likelihood estimator for Γ and $\bar{x}_g$ is the expectation of x conditional on group g .

The estimator for the variance of ability in group g is,

$$\hat{\sigma}_g^2 = \hat{\Gamma}' S_{xg} \hat{\Gamma} + \hat{\sigma}^2$$

where S_{xg} is the variance-covariance matrix of x conditional on group g .

Multiple imputations

While the institutional machinery of IRT-latent regression models estimated with marginal maximum likelihood could be used to yield estimators for group-level parameters of interest as described above, the widespread interest in analyzing LSES data prompts a more accessible approach to analysis.

To aid in secondary user analysis and allow for official results to be easily replicated by secondary users, LSES use imputation methods to produce imputed values for latent proficiency. The intention underlying the use of imputed values is to allow secondary users to calculate estimates for group-level parameters of interest that are consistent with the IRT-latent regression estimators described above, but with more familiar statistical methods.

While methods to produce a single imputed value for latent proficiency for each respondent are available, methods involving multiply imputed values are generally recommended when there is substantial uncertainty in the imputation (Sinharay et al., 2001). Specifically, the method of multiple imputation (Rubin, 1987) is commonly recommended as a statistically principled approach for dealing with missing data (e.g., Schafer and Graham, 2002), enabling consistent estimation of parameters in data with missingness under the assumption the missing data is missing at random (MAR; Rubin, 1976).

Multiple imputation has two benefits over many other imputation methods. First, multiple imputation is justified by statistical theory, in contrast to some common methods that are ad hoc and generally produce invalid inferences such as mean substitution (Rässler et al., 2013). Relatedly, these common methods produce estimates that are inconsistent with the IRT-latent regression estimators. Second, the use of multiple imputations instead of a single imputation both reduces the uncertainty in estimates associated

with the imputation process as well as enables the uncertainty due to imputation to be accounted for in the standard errors (Rubin, 1976; Sinharay et al., 2001). As a result, the institution sponsoring the large-scale assessment creates the imputed data for both official and secondary user analysis and reporting. The institution packages the imputations in data products for secondary users for them to replicate published reports and create new ones of their own. This serves as a measure that provides transparency to the officially reported results and allows for external quality control and verification of the reports.

A key concept in multiple imputation is congeniality, where the analysis model applied to the imputed data must correspond to the imputation model used to generate the imputed values (Meng, 1994). For example, consider a regression analysis where some values on the outcome variable are MAR. Multiple imputation may be used to impute values for these missing responses, allowing an institution to provide a completed dataset to secondary users. While the imputed values are generally not the responses that would have been observed, the secondary user may still conduct the regression analysis with the imputed values and obtain the correct regression parameter estimates. In this context, congeniality would be guaranteed if the predictors used by the secondary user were also used as predictors in a regression-based imputation model (Meng, 1994).

Generation of plausible values

Multiple imputation is usually applied to impute values for missing responses on observed variables (Rubin, 1987). Mislevy's (1991) insight was that the latent variable in IRT representing ability may be considered a variable missing for all test takers. As missingness on the latent variable in IRT is guaranteed to be MAR, the assumption underlying multiple imputation, values may be imputed on the latent variable for all test takers. With values imputed for the latent variable, secondary users may apply standard statistical methods that require complete data, such as least-squares regressions and *t*-tests. With plausible values, the challenges associated with the latency of ability and the massive amount of missingness in the item responses are eliminated for the secondary user.

Specifically, plausible values are generated as random draws from an approximation to each test taker's conditional ability distribution,

$$f(\theta_i | x_i, \gamma_i, \beta, \Gamma, \sigma^2) \propto \prod_{j \in S_i} P(Y_j = y_{ij} | \theta_i, \beta_j) f(\theta_i | \Gamma, \sigma^2, x_i)$$

Multiple plausible values are drawn for each test taker to account for uncertainty in the test taker's ability. Specific details and approximations made in this procedure are provided in the technical documentation for each program (e.g., National Center for Education Statistics, 2018; Organization for Economic Co-operation and Development, 2016, 2018), and may differ between programs.

In the context of LSES, the requirement of congeniality implies that in order to support a potential secondary user's analysis involving estimating the mean ability for a given group, a dummy coded variable indicating membership in the group should be accounted for in the IRT-latent regression model (Mislevy, 1991). For example, a categorical ethnicity variable with seven categories may be converted into six dummy coded variables, with one category treated as the reference category and one dummy coded variable indicating membership in each of the other six categories. To account for the dummy coded variable, the variable may be included as a predictor in the regression (within x). But if the variable is independent of ability conditional on the predictors included in the regression, the variable does not need to be included (Meng, 1994; Mislevy, 1991). Note that the amount of bias that may be introduced by a non-congenial analysis is not only dependent on the magnitude of the relationship between ability and that variable unaccounted for by the variables included in the regression model, but also the reliability of the cognitive assessment (Marsman et al., 2016).

To account for many potential secondary user analyses, many predictors are typically included in the IRT-latent regression model (Mislevy, 1991). This follows generally recommended practices in the multiple imputation literature that support being as inclusive as possible in constructing the imputation model (Collins et al., 2001). To reduce overfitting, principal component analysis is typically applied to the full set of contrast-coded contextual variables as a data reduction technique. In practice, the predictors in the regression are the subset of the principal components that explain a predetermined amount of variance in the contextual variables (von Davier et al., 2006).

While LSES may have been the earliest use of multiple imputation for latent variables (see Rubin, 1996), the method has been applied more widely in other latent variable contexts more recently (e.g., Boeschoten et al., 2018; Carlin, 1992; Dicke et al., 2015; Gortler et al., 2015; Joinson et al., 2012; Rhee et al., 2013). The popular structural equation modeling software Mplus, for example, enables researchers to generate plausible values for a large class of latent trait models (see Asparouhov and Muthén, 2010). Many of these applications employ plausible values for the purpose of missing data treatment even in primary user analysis, as recommended by some authors (Bray et al., 2015; Graham, 2003), similar to how multiple imputation is often used as a general purpose missing data treatment with missingness in observed variables (Schafer and Graham, 2002; Sinharay et al., 2001).

Interpretation of plausible values

While this chapter describes the history of plausible values as a generalization of Rubin's multiple imputation methodology for missing data, plausible values may also be understood within a Bayesian framework without reference to missing data. Here,

plausible values are random draws from each test taker's ability distribution conditional on their item responses, contextual information, and the IRT-latent regression model parameter estimates.

Within this framework, the distinction between plausible values in large-scale educational assessments and conventional latent scores used in individual-score assessments is clarified:

- (1) Plausible values are random draws from each test taker's conditional ability distribution, which may be associated with greater bias and error for individual-level inference than some other statistics such as the mean or mode (expected a posteriori, EAP, or maximum a posteriori, MAP, respectively; [Mislevy et al., 1992](#)).
- (2) Plausible values in LSES are drawn from ability distributions conditional on both item responses and contextual information. As the contextual information is not part of the assessment, individual-level inference with these plausible values may be inappropriate and unfair.

Notably, with either interpretation of plausible values—as either multiply imputed values for the missing ability variable or as random draws from each test taker's conditional ability distribution—the same key conclusions are reached. Within the multiple imputation interpretation, plausible values are intermediate values that may be used in place of ability scores so that simple statistical methods such as *t*-tests may be applied in order to reproduce the results from the IRT-latent regression imputation model. As imputations of missing values, plausible values for any given test taker may not best represent the ability of the test taker. Within the Bayesian interpretation, plausible values are not statistically optimal for individual-level inference and may not facilitate fair individual-level inference due to the incorporation of contextual information in the plausible value generation. With both interpretations, plausible values are used to calculate estimates of summaries of latent ability distributions, conditional on contextual variables of interest, but are not suited for individual-level inference.

Analysis of plausible values

Plausible values, or multiple imputations more generally, result in M complete datasets: one for each set of imputations. A general principle in the analysis of plausible values is that each of the M complete datasets may be analyzed with standard complete-data analysis methods, as if latent ability for every test taker had been directly observed and recorded. Once the standard complete-data analysis method has been applied to each of M complete datasets, the results are averaged across the datasets to produce the final point estimates.

For example, an estimate of the mean of latent ability for a group g is calculated within each set of plausible values,

$$\hat{\mu}_g^{(m)} = \left(\sum_{i \in s_g} w_i \right)^{-1} \sum_{i \in s_g} w_i \hat{\theta}_i^{(m)}$$

where $\hat{\mu}_g^{(m)}$ is the estimated ability mean for group g using the m th set of plausible values, s_g is the set of all test takers in group g , $\hat{\theta}_i^{(m)}$ is the m th plausible value for test taker i .

Once M estimates are obtained, these estimates may be averaged to obtain the final estimate,

$$\hat{\mu}_g = \frac{1}{M} \sum_{m=1}^M \hat{\mu}_g^{(m)}$$

This procedure can be applied more generally to other types of statistics,

$$\hat{G}_g(\hat{\theta}) = \frac{1}{M} \sum_{m=1}^M \hat{G}_g^{(m)}(\hat{\theta})$$

For example, $\hat{G}_g(\hat{\theta})$ could be a standard deviation, so

$$\hat{G}_g^{(m)}(\hat{\theta}) = \sqrt{\left(\sum_{i \in s_g} w_i - 1 \right)^{-1} \sum_{i \in s_g} w_i \left(\hat{\theta}_i^{(m)} - \hat{\mu}_g^{(m)} \right)^2}$$

And $\hat{G}_g^{(m)}$ could be the proportion of test takers within an achievement level, defined as ability within the range of $T_L \leq \theta < T_U$,

$$\hat{G}_g^{(m)}(\hat{\theta}) = \left(\sum_{i \in s_g} w_i \right)^{-1} \sum_{i \in s_g} w_i I(T_L \leq \hat{\theta}_i^{(m)} < T_U)$$

where $I(\cdot)$ is an indicator function that is 1 if the condition is satisfied or 0 otherwise.

The variance of the estimator is estimated as the sum of two components according to Rubin's rules ([Rubin, 1987](#)),

$$\widehat{\text{var}}(\hat{G}_g(\hat{\theta})) = \widehat{\text{var}}_{\text{WI}}(\hat{G}_g(\hat{\theta})) + (1 + M^{-1}) \widehat{\text{var}}_{\text{BI}}(\hat{G}_g(\hat{\theta}))$$

The first component, $\widehat{\text{var}}_{\text{WI}}(\widehat{G}_g(\widehat{\theta}))$, denotes the variance component within imputations (plausible values), and is calculated as the mean variance estimate with each set of imputations,

$$\widehat{\text{var}}_{\text{WI}}(\widehat{G}_g(\widehat{\theta})) = \frac{1}{M} \widehat{\text{var}}_{\text{WI}}^{(m)}(\widehat{G}_g(\widehat{\theta}))$$

where $\widehat{\text{var}}_{\text{WI}}^{(m)}(\widehat{G}_g(\widehat{\theta}))$ is the estimated variance of $\widehat{G}_g(\widehat{\theta})$ when estimated from the m th set of plausible values.

To account for the complex sampling design in large-scale assessments, replicate weights from a resampling procedure such as the jackknife (Rust and Johnson, 1992) are provided by the institution for use in the calculation of the within-imputation variance component,

$$\widehat{\text{var}}_{\text{WI}}^{(m)}(\widehat{G}_g(\widehat{\theta})) = \sum_{p=1}^P \left(\widehat{G}_g^{(m,p)}(\widehat{\theta}) - \widehat{G}_g^{(m)}(\widehat{\theta}) \right)^2$$

where $\widehat{G}_g^{(m,p)}(\widehat{\theta})$ is the estimate calculated using the m th plausible value and the p th replicate weight.

In practice, the within-imputation variance component may be approximated using the estimated variance component based on the first plausible value only (as done in NAEP; von Davier et al., 2006) as

$$\widehat{\text{var}}_{\text{WI}}(\widehat{G}_g(\widehat{\theta})) \approx \widehat{\text{var}}_{\text{WI}}^{(1)}(\widehat{G}_g(\widehat{\theta}))$$

The second component $\widehat{\text{var}}_{\text{BI}}(\widehat{G}_g(\widehat{\theta}))$ denotes the variance component between imputations (plausible values), and is calculated as

$$\widehat{\text{var}}_{\text{BI}}(\widehat{G}_g(\widehat{\theta})) = \frac{1}{M-1} \sum_{p=1}^P \left(\widehat{G}_g^{(m)}(\widehat{\theta}) - \sum_{m=1}^M \widehat{G}_g^{(m)}(\widehat{\theta}) \right)^2$$

Accessible introductions including practical examples on analyzing plausible values include Mislevy et al. (1992), von Davier et al. (2009), and Wu (2005).

Extensions and advances in analysis methodology

Bridge study designs

Given the emphasis on the comparability of results from assessments administered in different years, LSES balance two competing pressures (Beaton, 1990a). First, the pressure to maintain equivalence in the measurement instrument across years to minimize confounding by instrument differences (Beaton, 1990b). Second, the pressure to adapt to changes in the interaction of test takers and the measurement instrument, changes in the skills and knowledge most relevant to stake holders, and methodological advancements (Zwick, 1992).

When changes to the assessment or administration are required, a bridge study is typically employed to study the impact of these changes and to link results from the new administration to results from previous administrations. For example, NAEP has employed bridge studies to link results after transitioning to assess each student in only one subject area (Johnson and Zwick, 1990), standardizing and redesigning the NAEP long-term trend assessments (Perie et al., 2005), and more recently, transitioning from a paper-based assessment to a digitally based assessment (Jewsbury et al., 2020, 2021a).

While bridge studies can differ in methods to evaluate the impact of the changes and to link the results, the most common approach is to administer the new and previous administrations to two randomly equivalent samples. With randomly equivalent samples, the impact of the change may be evaluated without confounds from population differences. Furthermore, a common population linking method may be employed to link the results (Mazzeo and von Davier, 2013; Yamamoto and Mazzeo, 1992). Common population linking assumes that the new administration still measures the same construct as the previous administration and that both samples have been drawn from the same population. The theoretical properties of error introduced by such linking, as well as methods to extend the conventional approach to LSES variance estimation to account for linking in bridge studies, can be found in Jewsbury (2019).

Adaptive testing designs

With the transition of several LSES to digitally based assessments, interactive assessments where item selection adapts to the performance of the test taker in real time become possible. Such designs are referred to as computerized adaptive tests (CATs) and serve to increase measurement precision by selecting items during the assessment that are more informative about ability (Wainer et al., 1990).

To balance content and quality control in LSES, instead of adapting after each item, adapting after blocks of items may be preferred (Oranje et al., 2014; Yamamoto et al., 2018). Block-level adaptive tests are known as multistage tests (MSTs), and have been implemented in PISA and PIAAC (Yamamoto et al., 2018). Introducing MST to the 2018 PISA assessment improved measurement precision of individual test takers by 4–5% (Shin et al., 2021).

Latent trait models, such as IRT used in LSES, enable the design and analysis of adaptive tests (Lord, 1980; Wainer et al., 1990). As described earlier in this chapter, LSES methodology involving marginal maximum likelihood estimation allows for missing data in the item responses provided that the missing data is missing at random (MAR). Missing data resulting from adaptation in an adaptive test is MAR provided that the model used to estimate the item parameters is appropriate with respect to the features of the adaptive test design (e.g., Eggen and Verhelst, 2011; Jewsbury and van Rijn, 2020, 2021).

Process data

Process data are data that describe cognitive and behavioral processes and are a new type of contextual information that may be collected by digitally-based LSES (Bergner and von Davier, 2019; Ercikan and Pellegrino, 2017; Nicolay et al. this volume). Examples of process data are response time, and the sequence of actions a test taker took in completing an item. Process data has substantial utility to improve the reliability and validity of assessments. For example, to evaluate motivation and effort (Michaelides et al., 2020); to screen for data quality (Yamamoto and Lennon, 2018); and to inform missing data treatment and identification of guessing behaviors (Ulitzsch et al., 2020a,b). In addition, process data may help contextualize ability differences between groups and years, and inclusion of process data in the imputation model for the plausible values may reduce non-congeniality related biases in the results by contributing to the explanation of ability (von Davier et al., 2019).

Process data is methodologically distinct from traditional contextual variables, as process data may not be measured independently of the item responses. Consequently, the assumption of conditional independence between item responses and contextual variables given ability, made in the IRT-latent regression (Mislevy, 1984, 1985), may be less reasonable for process data. For example, use of the correct strategy to solve an item may be directly related to the accuracy of the response, even after controlling for ability.

Response time is a type of process data that has been extensively studied (e.g., Molenaar et al., 2015; van der Linden, 2007; van Rijn and Ali, 2018). The issue of potential conditional dependences between item responses and response time has been considered, and several models to jointly model item responses and response time while accounting for conditional dependencies have been proposed (e.g., Bolsinova et al., 2017; Bolsinova and Molenaar, 2018; Molenaar et al., 2016).

While models that account for item response and process data conditional dependencies are available (De Boeck and Jeon, 2019), the applicability of these models to the methodology in LSES is less clear. While IRT-latent regression models that include parameters to account for conditional dependencies have been proposed, accounting for the conditional dependencies in the analysis of plausible values may not be straightforward (Jewsbury et al., 2021b). In the context of response time, the conditional dependencies are small relative to the improvement in the measurement of ability, potentially justifying inclusion of response time into the IRT-latent regression model even if the conditional dependencies are not modeled (Shin et al., under review; Shin et al., in press). However, this result may not generalize to other types of process data, and the accumulation of conditional dependencies from inclusion of many process data variables may result in non-negligible estimation biases.

Questionnaire matrix sampling

Many LSES collect additional contextual information about the test taker through a questionnaire, often administered after the cognitive assessment. While the cognitive assessment is generally matrix sampled, the questionnaire typically involves only one form administered to every test taker. This questionnaire form is necessarily constrained in length, given time constraints on assessment time and findings that lengthy questionnaires reduce response quality (Galesic and Bosnjak, 2009). Consequently, administering one of multiple questionnaire forms to each test taker has been proposed to increase the total number of questionnaire items administered. These forms may involve a matrix sampling design, akin to the cognitive assessment, to ensure all pairs of items are observed (Bertling et al., 2016a).

Early work proposed and evaluated modeling approaches for questionnaire matrix sampling designs (Adams et al., 2013), and several concerns were raised about the validity of these approaches (von Davier, 2013). In particular, concerns were raised that questionnaire matrix sampling necessarily introduces missing data into the questionnaire responses and therefore the predictors in the IRT-latent regression. The standard approach to missing data in the predictors in LSES, the missing indicator method (Cohen et al., 2014), can introduce bias into the regression coefficient estimates (Jones, 1996; Rutkowski, 2011; Rutkowski and Zhou, 2015). However, Grund et al. (2021) recently showed that the use of the missing indicator method in the IRT-latent regression can facilitate unbiased estimation with plausible values, provided that the missing data is MCAR and that the plausible value analysis uses pairwise estimation.

Several alternative approaches have been proposed to the missing data indicator method. Kaplan and Su (2016, 2018) evaluated imputing the missing data on the predictors prior to the IRT-latent regression and showed that bias in reproducing correlations depended more on the matrix sampling design than the imputation method. Weirich et al. (2014) showed that a two-stage multiple imputation involving multiple imputations for the questionnaire missingness prior to the imputation of ability was superior to the use of a single imputation. Finally, when test takers receive items for all questionnaire constructs (or scales), but only a subset of items for any given construct, construct scores may substitute for the original questionnaire response variables in the IRT-latent regression (Shin et al., in preparation).

Alternatives to plausible values

Plausible values generated from IRT-latent regression models are an excellent solution to the design issues common in LSES. Plausible values provide analysts with numbers for latent ability that enable analysis with standard statistical methods commonly available in general purpose statistical software. Complexities associated with the latency of ability, as well as missing data due to both matrix sampling and potentially adaptive testing, are resolved by the institution prior to the analysis. Furthermore, plausible values are particularly suited for group-level inference over common alternative scores. For example, the distribution of common IRT-based scores such as maximum likelihood estimates (MLEs) and expected a posteriori scores (EAPs) can substantially diverge from the distribution of ability (Mislevy et al., 1992), making these scores suboptimal for group-level inference.

Plausible values do, however, have two notable limitations. First, while plausible values were motivated to simplify analysis, plausible value-based analysis is still relatively complex. Recommended use of plausible values, as described above, requires repeating the analysis multiple times for each set of plausible values and each replicate weight. Accounting for bridge study linking designs is a further complication in standard error calculation on certain trend comparisons (Jewsbury, 2019). Plausible values are also theoretically complex, with issues such as the meaning of plausible values, the use of contextual information to generate plausible values, and that different estimates of ability may be suited for different levels of inference, which has necessitated several tutorials on plausible values (e.g., Braun and von Davier, 2017; Mislevy et al., 1992; Wu, 2005). With the rise in popularity of structural equation modeling and associated software (e.g., Mplus, Muthén and Muthén, 2017), many contemporary analysts may be more familiar with IRT-latent regression, a type of structural equation model, than plausible values.

Second, the requirement that all inferences are conducted with a single dataset of plausible values places technical constraints on the institutional analysis of LSES. While institutions intend to ensure as many analyses as possible are approximately congenial with the IRT-latent regression imputation model (Mislevy, 1991), risk of overfitting the IRT-latent regression model may limit how many analyses can be accommodated. Not all contextual variables may be accommodated, and not all uses of those contextual variables may be supported (e.g., Schofield et al., 2015). Finally, certain extensions such as some methods to better handle missing data in the contextual variables (von Davier, 2013) and model process data and item response dependencies (Bolsinova et al., 2017) may be difficult or impossible to implement with plausible value methodology.

Several methods as alternatives to plausible values could be implemented via user-friendly tools to conduct analysis directly with the item response data. For example, the National Center of Education Statistics (NCES) and the Organization for Economic Co-operation and Development (OECD) provide Data Explorers of various surveys (see List of Relevant Websites, below). The Data Explorers can be used to conduct numerous common analyses online. While such tools involve the analysis of plausible values, the tools could be modified to conduct an IRT-based analysis using a model customized for the desired inference. This approach would provide institutions greater flexibility to incorporate methodological advances and innovations, while avoiding any constraints required to support plausible value-based analysis.

Concluding remarks

This chapter describes the core methodology common across many LSES. The core methodology, analysis based on plausible values generated from IRT-latent regression models, was described. Select extensions to the methodology and current areas of research were summarized. Note that summarizing several ongoing research areas was beyond the scope of this introductory chapter, such as analyzing locally dependent item responses and multidimensional constructs (e.g., von Davier et al., in press), research on hierarchical latent regression (e.g., Li et al., 2009), fully Bayesian estimation (e.g., Johnson and Jenkins, 2004), model selection (e.g., Culpepper and Park, 2017), and alternate methods that relax technical assumptions in the estimation (e.g., Andersson and Xin, 2021; von Davier and Sinharay, 2010).

Extensions to the LSES methodology may be categorized as either evolutionary or revolutionary. Evolutionary extensions advance the method in terms of either power or flexibility, but maintain the constraint that analysis is conducted with plausible values. Revolutionary extensions consider approaches that are not premised on the use of plausible values. Underpinning any discussion of LSES methodology is LSES assessment design: plausible values were developed to support group-level inference when individual-level reliability of the assessment is low (Mislevy et al., 1992). While alternatives to the assessment design of LSES is not considered in this chapter, assessment designs that ensure an adequate minimum level of individual-level reliability may facilitate other methodological approaches. For example, the replacement of plausible values with another score that is approximately distributed as ability under these conditions (e.g., weighted likelihood estimates, WLEs; Warm, 1989).

Regardless of the approach taken, LSES methodology remains an active and exciting area of research. Indeed, since the original introduction of the LSES core methodology (Mislevy, 1984, 1985, 1991), LSES remain one of the most prominent examples of advanced psychometrics (Oranje and Kolstad, 2019).

Glossary

Criterion-referenced A comparison of performance to a fixed standard, such as the knowledge and skills an assessment is designed to measure, without regard to the performance of others

Cut score The point that separates one level of performance from another (e.g. “proficient” vs. “not proficient”) on a score scale

Feedback data Data provided to panelists during the standard setting meeting to help inform their cut score judgments

Impact data The percentage of examinees classified into each performance level, based on a set of cut scores

Norm-referenced A comparison of performance to the performance of others, such as comparing one examinee’s score to the scores of a reference group of examinees

Performance level A scale score range, bounded by the minimum scale score, the maximum scale score, and/or the cut scores, which reduces the granularity of scores to facilitate score interpretation

Performance level descriptors (PLDs) A qualitative description of the knowledge and skills represented by a given performance level. Another common name for these is “achievement level descriptors.”

Standard setting A process that typically uses stakeholder judgments and data to determine cut scores that signify different levels of performance on an assessment

Introduction

At one point or another, most people in modern society have had to take an assessment. Often the score received is only important in relation to a threshold one aims to surpass. For example, a score of 1250 is better than a score of 1200 on the SAT, but if the score needed to be admitted to one’s first-choice university is 1300, the difference between 1250 and 1200 is of little relevance because

Fig. 1 The standard setting process.

neither score meets the threshold. Standard setting, the process of deriving those thresholds or cut scores, has been an area of concerted research focus in the psychometric community for decades, though it may remain opaque to the general public. New standard setting methods and refinements to existing methods continue to be developed in an ongoing effort to increase the reliability and validity of the resulting cut scores and performance levels.

This article provides a brief summary of the art and science of standard setting (Cizek, 2001). Fig. 1 provides an overview of the standard setting process and of the structure of this article. In most cases, standard setting is conducted through meetings with subject-matter experts. This article begins with a discussion of the activities that must be completed prior to a standard setting meeting. Next, the typical flow of activities during a standard setting meeting is described along with a few common methods used for standard setting. Finally, post-standard setting meeting activities are detailed, including standards articulation, stakeholder approval, and finalizing performance level descriptors (PLDs). For readers who are interested in learning more about particular standard setting methods or activities, Cizek and Bunch (2007) and Cizek (2012b) provide book-length treatments of these topics.

Pre-standard setting meeting activities

This section describes several of the most common activities that occur prior to a standard setting meeting, including:

- establishing the purpose and goals of standard setting,
- engaging stakeholders,
- developing preliminary performance level descriptors (PLDs),
- selecting a standard setting method,
- analyzing data, and
- preparing materials.

Establishing the purposes and goals of standard setting

Many decisions need to be made during the standard setting design process, including selecting a standard setting method and planning for a standard setting meeting. However, making these decisions without first understanding the reasons why performance levels are desired is difficult. For example, users of certification assessment scores may want a single cut score that differentiates passing performance from failing performance. This cut score is used to classify examinees as qualified or unqualified for a particular occupation. The cut score will have to be justified, based on job analysis information and predictive validity evidence, to provide evidence that examinees who fail are truly unqualified for a particular job and that examinees who pass are qualified for the job and will likely be successful at it. If a previous version of the assessment exists, there may also be an implicit assumption that the pass rate on the new assessment will be similar to the previous pass rate.

Setting standards on an assessment that is required for statewide summative accountability purposes, on the other hand, requires having at least two cut scores, separating students into three performance levels, per federal requirements (Every Student Succeeds Act, 20 U.S.C. § 6301, 2015), and states that have had four or five performance levels may want to have the same number of categories on a new or revised version of their assessment. These assessments are federally required to be “criterion-referenced”—tied to performance relative to the state’s academic content standards. Nevertheless, policymakers often have “norm-referenced” assumptions about the percentages of students expected to score within each category, and substantial deviations from the expected percentages may be politically untenable.

Those who are responsible for facilitating a standard setting meeting must understand the myriad of purposes for which assessment results, and especially performance levels, are likely to be used. Working with policymakers and test-score users is a critical first

step in understanding the purposes and goals of the standard setting endeavor and designing a standard setting process that will achieve those goals.

Stakeholder engagement

There are two very important groups of people to engage with prior to a standard setting meeting. The first group is the group of stakeholders who have ultimate responsibility for setting the cut scores. Understanding their priorities and what they view as acceptable, versus unacceptable, outcomes is important. Those in charge of facilitating the standard setting meetings should meet with decision-makers early and often and find ways to embed their priorities into the standard setting process so that everyone is working toward a common goal.

The second group of people to engage with is the group of panelists who will be involved in the standard setting process. There are three important considerations when determining the composition of the standard setting panel:

1. What are important stakeholder groups to include?
2. What knowledge or skills do individuals need in order to contribute to the standard setting process?
3. How many panelists should be included on the panel?

Although examinees are rarely included in a standard-setting panel, subject-matter experts and other individuals who will be impacted by the cut score placement should be included in the process, so that their perspectives are included, they buy into the process, and they endorse the results. Groups to be represented on standard setting panels will differ, depending on the type of assessment. For example, for a statewide summative assessment, teachers are an essential group to include on the standard setting panel because they should be familiar with the state standards to which the assessments align, the students who will take the assessments, and the ways in which scores are used. Other relevant panelists might include curriculum specialists, school board members, and community members.

Decision-makers will want recommended cut scores to be based on the informed judgments of subject-matter experts, and, ideally, they will want to be able to accept those recommendations. If decision-makers reject the recommendations, they risk alienating standard setting panelists and the groups they represent. Therefore, careful panelist selection and facilitation that keeps all stakeholders aligned toward the same goals are needed in order to ensure the success of the standard setting process.

There are no strict criteria for determining the number of panelists needed for a standard setting meeting. However, the number of panelists must be sufficient to ensure diverse stakeholder representation across geographic or other background characteristics, and inclusion of necessary expertise. Often, past precedent (e.g. 10 panelists were included during a previous standard setting, so approximately 10 panelists will be included again) and budget constraints also factor into panel size.

Standard setting meetings are often multi-day or even weeklong events; getting this degree of time commitment requires advance planning, and sufficient time must be allotted for panelist recruitment. Depending on how large and diverse the panelist group should be, in terms of both demographics and subject-matter expertise, recruiting enough willing panelists with desired characteristics may take several months. Once panelists are recruited, it is important to carefully coordinate communications so that they remain engaged. The most important communications are those that establish the legitimacy and importance of the process and provide all of the logistical details that panelists need, such as information about meeting location, travel arrangements, lodging arrangements, and per diems. Loomis (2012) provides thorough descriptions of pre-meeting recruitment and communications with panelists.

Developing preliminary performance level descriptors

Cut score recommendations are typically an output of a standard setting meeting, but the number of expected levels, and descriptions of what those levels should mean, must be established ahead of time. Policymakers, sometimes in conjunction with various stakeholder groups, determine the number of performance levels, based on the goals of classifying examinee performance and the number of performance levels into which examinees can be meaningfully differentiated. For some tests, two performance levels are sufficient. In many large-scale educational assessments, four or five performance levels are common.

Each performance level typically has an associated label, such as “proficient,” that provides a shorthand description of the level (Perie, 2008; Zieky and Perie, 2006). Policymakers should select labels that are clear, concise, and accurate; that avoid ambiguity; and that they are comfortable putting in front of the public. Table 1 lists performance level labels for a variety of assessments (international, national, and state).

Performance level descriptors (PLDs), also known as achievement level descriptors, communicate the knowledge and skills that examinees performing at each performance level possess and how this knowledge deepens at higher performance levels (Perie, 2008; Schneider and Egan, 2014). PLDs are often viewed as the heart of the standard setting process (Egan et al., 2009) because panelists must understand what performance levels mean in order to classify examinees (and/or test items) into each level.

Egan et al. (2012) define four types of PLDs, each with a different goal and purpose in the standard setting process:

1. Policy PLDs: General statements about the knowledge and skills demonstrated by examinees performing at a given level and that communicate policymakers’ vision for the performance levels.
2. Range PLDs: Detailed descriptions of the knowledge and skills embodied within a performance level.

Table 1 Performance level labels for international, national, and state assessments.

Assessment	Lowest level	←————→			Highest level
Trends in International Mathematics and Science Study (TIMSS)	Low	Intermediate	High	Advanced	
National Assessment of Educational Progress (NAEP)	Below basic	Basic	Proficient	Advanced	
Smarter Balanced Assessment Consortium (SBAC)	Standard not met	Standard nearly met	Standard met	Standard exceeded	
Florida Standards Assessments	Inadequate	Below satisfactory	Satisfactory	Proficient	Mastery
Georgia Milestones	Beginning learners	Developing learners	Proficient learners	Distinguished learners	
Ohio's State Tests	Limited	Basic	Proficient	Accelerated	Advanced
State of Texas Assessments of Academic Readiness (STAAR)	Did not meet grade level performance	Approaches grade level performance	Meets grade level performance	Masters grade level performance	
Virginia Standards of Learning (SOL)	Fail/below basic	Fail/basic	Pass/proficient	Pass/advanced	

3. Target PLDs: Descriptions of the minimum level of performance for a given performance level.
4. Reporting PLDs: Concise versions of the range PLDs, used to communicate the meaning of the performance levels to examinees and the public.

Not all types of PLDs are developed for all assessment programs. The goals of the assessment, the standard setting method, and how performance is reported determine the types of PLDs needed. For example, some standard setting methods require the identification of the knowledge and skills of an examinee performing at the minimum level or the bottom of each performance level; these examinees are sometimes referred to as “borderline” examinees (Downing, 2006; Zieky and Perie, 2006). For these methods, target PLDs are needed (Schneider and Egan, 2014); for other methods, target PLDs are not needed.

Preliminary PLDs developed to support the standard setting meeting are typically refined using the final set of cut scores (Perie, 2008). For K–12 assessments where content standards are grade-specific, PLDs will necessarily be grade-specific, and attention should be paid to the knowledge and skills that students need at a performance level at a given grade, to ensure that the knowledge and skills represent a progression across grade levels (Perie, 2008; Zieky and Perie, 2006).

Selecting a standard setting method

Many approaches to setting performance standards exist. Some are better suited than others for a given assessment, based on identified goals or item types used, but there is no one right method (Egan et al., 2009; Ferrara et al., 2014). However, the selection of the method should occur early in the standard setting planning process, so that necessary components of the method can be planned for and carried out at the appropriate times (Downing, 2006). The method identified for use should allow for defensible performance standards, aligned with the purpose and content of the test and with the number of performance levels. A description of several common standard setting methods is provided later in this article.

Data analysis

During the standard setting meeting, data are often presented to panelists to inform their judgments. These data are called “feedback data” and are carefully curated to help facilitate panelists’ judgmental process. Depending on the type of standard setting method employed, various graphical plots and/or descriptive statistics may be provided to panelists during the standard setting meeting, to help them understand how their judgments would be translated into cut scores and to illustrate the consistency of judgments within the panel. These feedback data are prepared during the standard setting meeting, using panelist judgments as input. Analytic code should be developed and validated prior to the standard setting meeting, to automate analysis of panelist judgments so that results can be turned around quickly. This code should be well tested, using a variety of hypothetical human judgments, different numbers of panelists, different agreement levels among panelists, and other potential scenarios, to verify that it will run smoothly during the meeting. There should also be quality control checks built into the process. For example, a lower performance level requires a lower cut score than a higher performance level. If a panelist’s set of judgments are not internally consistent, their judgments should be flagged immediately, so that the facilitator can follow up with the panelist and receive corrected judgments. If a panelist does not provide one or more needed values, this should also be flagged for follow-up.

Some feedback data requires analysis of examinee scores prior to the standard setting meeting. Two common examples are item difficulty, quantified as the percent of examinees who answered each item correctly (i.e. item p -values), and impact data, which is the percentage of examinees classified into each performance level based on a given set of cut scores. For some methods, item maps must be generated, in such a way that each item is located on the score scale. The standard setting method, the availability of

data, and the standard setting philosophy play important roles in determining what types of feedback data to include in the standard setting meeting. For example, a philosophical approach that views standard setting as a primarily content-oriented endeavor implies measuring what examinees know and can do only in reference to the relevant standards. Therefore, providing impact data may be viewed as an incongruent norm-referenced method. Additionally, normative data on examinee performance may not be available at the time of a standard setting meeting, which will eliminate the ability to provide impact data and item difficulty information as feedback data to panelists.

It is increasingly common for standard setting to involve several studies prior to the standard setting meeting, to provide additional context for making judgments. These studies require careful planning and much longer timelines. Methods such as the Briefing Book method (Haertel et al., 2012) and the Benchmark method (Phillips, 2012) elevate the importance of external data in the standard setting process. Although study reports should be written and provided to interested audiences, and studies are often described in detail for the Briefing Book method, study results must often be summarized in concise visuals, so that panelists can see, at a glance, how their recommendations compare to study information. Elements of these methods are often blended with the Bookmark method (Lewis et al., 2012), because it is especially easy to illustrate particular benchmarks and external sources of data by associating benchmarks with specific items in an ordered item booklet (OIB).

Examples of potential analyses that could be used to inform cut scores include:

- comparisons to performance on a previous assessment system;
- comparisons to performance on other relevant assessments or measures (e.g. course grades);
- grade-to-grade comparisons using vertical scale scores and/or impact data; and
- contrasting groups (e.g. have college students take an end-of-course high school assessment and identify the score that best differentiates students who receive a B or better from students who do not).

Even with years to prepare, most testing programs will approach standard setting with incomplete or inadequate data. Item statistics from stand-alone field tests where examinees are not motivated to do their best, legacy items that only partially align with new PLDs, and idiosyncratic field-test populations are common issues that can sow confusion in standard setting panel meetings, and bias in the cut scores, if left unaddressed. Gaertner and Powers (2021) view these issues as missing data problems and offer suggestions, based on results from simulation studies, on potential approaches to address them.

Preparing materials

Some materials needed for a standard setting meeting are specific to the standard setting method selected. For example, an OIB is used for some standard setting methods (e.g. the Bookmark method), but not others. Likewise, examinee work samples are needed for some standard setting methods (e.g. the Body of Work method), but not others. Therefore, standard setting materials should be prepared after a standard setting method has been selected. Materials that are typically prepared for a standard setting meeting include meeting agendas, panelist and facilitator trainings, assessment items and/or OIBs, examinee performance data, preliminary PLDs, panelist judgment forms, and panelist evaluation surveys.

Typical standard setting meeting activities

In most cases, standard setting is conducted through meetings with subject-matter experts. Standard setting meetings for most methods include four key phases, each of which is discussed in this section:

- introduction to the purpose of standard setting,
- training on the standard setting method,
- content experts making judgments, and
- concluding activities (e.g. collection of secure materials, and evaluation).

At the start of the standard setting meeting, panelists should be oriented to the purposes and goals of the assessment and of the meeting. Providing panelists with appropriate background information and training is critical for ensuring that they understand the importance of their task, they are aware of the uses and consequences of the cut scores informed by their recommendations, and that they buy into the procedures and results of the meeting (Schafer, 2005).

The introduction often includes panelists “experiencing the assessment.” During this activity, panelists review each item, or a subset of items, from the assessment and respond to it as if they were an examinee. For constructed-response items, panelists are not required to draft a complete response, but are encouraged to think about the knowledge and strategies that examinees would use to engage with the item. After responding to the items, panelists are given an answer key so that they can self-score the assessment. This activity is meant to give panelists a better feel for the examinee experience and the relative difficulty of the items contained on a test form. For some standard setting methods, the assessment items are provided in an OIB, in which items are ordered from least difficult to most difficult. Although the OIB does not reflect the examinee experience, it is a helpful tool for gaining further insight into the relative difficulty of test items.

Another important part of the introductory training is to familiarize panelists with preliminary PLDs. Understanding the intended meaning of the performance levels is critical for making informed judgments about the level that best describes particular items or examinees.

Following the introduction to the purpose of the standard setting meeting, panelists should be trained on the method being used (Raymond and Reid, 2001). This training typically involves practicing the judgment activity at the center of the standard setting method, with opportunities for questions and clarifications. During the practice activity, explicit connections should be made between the PLDs and the judgments to be made (Ferrara and Lewis, 2012). The judgments that panelists make determine the numerical boundaries that separate performance levels. The mechanics for how the judgments are translated into cut scores should be explained and illustrated. Understanding of the process should be confirmed by all panelists, typically using a survey, prior to moving forward to the first round of judgments.

Once panelists are trained to use the standard setting method, they typically apply the method in 2–4 rounds of judgments, with discussion and feedback data provided between each round. Feedback data may include information about the consistency of panelist judgments, item performance, and/or examinee performance. Judgments may be inconsistent at the beginning of the process, resulting in a wide range of potential cut scores. Across rounds, panelists may revise their judgments based on discussion and feedback data. These revisions tend to improve the consistency of judgments across panelists. Exact consensus across panelists is almost never required, but a fairly narrow range of cut score recommendations is desirable because it suggests that panelists have developed a common understanding of the standard setting method and the meaning of the performance levels. It also means that the final recommended cut scores will not be far from any panelist's judgment, which promotes panelist acceptance of the final results.

Following the last round of judgments, panelists should be given a survey to evaluate the standard setting activities, including the degree to which they agree with where the performance standards were set (Cizek and Bunch, 2007). Results from this survey, in conjunction with results from the survey administered after the initial training and any other surveys administered over the course of the meeting, can be analyzed to provide data in support of the validity of the standard setting process (Hambleton and Pitoniak, 2006).

For many assessments, test security is an important consideration. In such cases, panelists should be briefed on test security requirements during the standard setting training. Panelists should be informed about their roles in ensuring test security and the consequences of violating security protocols. At the end of the meeting, all secure materials should be collected from panelists, ensuring that all items from all panelists are accounted for. Panelists should wait to be dismissed from the standard setting meeting by meeting facilitators after all materials are collected.

Common standard setting methods

The following sections provide brief descriptions of six common standard setting methods: the Angoff method and related methods, the Bookmark method, the ID Matching method, Embedded Standard Setting, the Contrasting Groups method, and the Body of Work method. Very detailed descriptions of these methods, and of several others, can be found in Cizek and Bunch (2007). Embedded Standard Setting is a relatively new method described in Lewis and Cook (2020).

Angoff and related methods

The Angoff method is a criterion-referenced process in which trained panelists make judgments about the number of points an examinee would need to earn on a test in order to be placed into a given performance level. For each performance level, each panelist independently reviews each item on the test and estimates the probability that a borderline or, equivalently, a minimally competent examinee would respond correctly to each item.

There are several variations on the Angoff method (Angoff, 1971), such as the modified yes/no procedure (Impara and Plake, 1997) and the extended Angoff procedure (Hambleton and Plake, 1995). The original method described by Angoff (1971) requires panelists to determine whether a borderline examinee would correctly answer each item, as indicated by a yes/no response. The cut score would be determined by converting "yes" responses to a value of 1 and "no" responses to a value of 0, summing the scores for each panelist, and averaging the total scores across the group of panelists (Impara and Plake, 1997). Table 2 provides an example of the yes/no version of the Angoff method.

Angoff (1971) provided a variation on the yes/no procedure that requires panelists to estimate the proportion of borderline examinees who would answer the item correctly. Despite being a footnote in the Angoff (1971) paper, this variation on the yes/no method is traditionally referred to as the Angoff method. The cut score is determined by summing the probabilities for the individual items. A hypothetical example of the Angoff method is provided in Table 3. This example shows five panelists' judgments for the probabilities of a borderline examinee responding correctly to each item on a 10-item test. The sum of the probabilities across all the items becomes each panelist's suggested cut score for the test.

The extended Angoff procedure applies to tests that include polytomous items (i.e. items worth more than one point). In this case, panelists answer the following question: "How many score points would the borderline examinee earn on this item?"

Once each panelist has provided a cut score, a single cut score based on the group of panelists must be determined. A common approach is to use the median of the panelists' cut scores; however, the mean (the average of all panelists' cut scores) or the trimmed

2	0.25	0.45	0.30	0.35	0.30
3	0.65	0.80	0.50	0.80	0.85
4	0.50	0.70	0.50	0.65	0.55
5	0.40	0.65	0.40	0.45	0.55
6	0.35	0.55	0.25	0.40	0.50
7	0.65	0.70	0.60	0.65	0.60
8	0.80	0.90	0.75	0.85	0.85
9	0.30	0.50	0.30	0.35	0.40
10	0.75	0.90	0.65	0.80	0.80
Sum/cut score	5.00	6.75	4.50	5.75	5.80

mean (the average of the panelists' cut scores, excluding highest and lowest cut scores) may also be used. The benefit of using the median or the trimmed mean is that any extreme outlier scores will not impact the final cut score. For the example in Table 2, the final cut score could be 5.56 (mean), 5.75 (median), or 5.52 (trimmed mean).

Bookmark method

The Bookmark method (Lewis et al., 1996) is a common alternative to the Angoff method. The defining feature of the Bookmark method is the OIB. Panelists select the point in the OIB at which they judge the items to be too hard for a borderline examinee more often than not. To quantify "more often than not," various response probability values have been used, including, most commonly, 0.5 and 0.67 (Lewis et al., 2012; Huynh, 2006). Panelists have generally reported understanding the Bookmark procedure (Lewis et al., 2012). The Bookmark method also allows for relevant feedback data to be easily included within the OIB. Such feedback data might include external benchmark information, so that panelists understand how their bookmark judgments, made in reference to target PLDs and conceptualizations of borderline examinees, relate to scores and to impact data on other relevant assessments.

For assessments with more than two performance levels, panelists must repeat the process of conceptualizing a borderline examinee and flagging an item in the OIB. For example, an assessment with four performance levels requires three cut scores, three definitions of a borderline examinee, and three bookmarks. For the Angoff method, panelists would have to assign three different probabilities to each item. The Bookmark method greatly simplifies this process by eliminating many of the item-level judgments needed. For example, after a panelist places a bookmark differentiating Level 1 from Level 2, there is no need for the panelist to consider harder items for the first cut score. Likewise, when determining where to set the bookmark that differentiates Level 2 from Level 3, there is no need to consider items that fall before the first bookmark in the OIB—these items have already been judged to be Level 1 items, so they are not relevant to determining the bottom of Level 3.

Although the streamlined bookmarking process saves substantial time for panelists, the success of the process depends heavily on a well-constructed OIB. Challenges with OIBs include difficulty imbalance and item-to-PLD mismatch. Difficulty imbalance occurs when there are gaps in item difficulty in the OIB and/or clusters of items with very similar difficulty within the OIB. Item-to-PLD mismatch occurs when content experts judge items to be ordered differently than their empirically derived order. Difficulty imbalance should be avoided when items are selected for the OIB. Item-to-PLD mismatch is more difficult to control for ahead of time, although having both stable item parameters and the right difficulty balance are essential. Even with well-developed OIBs, item ordering based on empirical data does not always align with panelists' notions of item difficulty.

Item-descriptor matching method

In contrast to the Angoff and Bookmark standard setting methods, the ID Matching method does not require panelists to envision a hypothetical borderline examinee and use this examinee to assist them in determining judgments. Instead, this method is focused solely on test content. At the heart of the ID Matching task is consideration of the PLD that most closely matches the knowledge and skills that examinees need in order to correctly respond to an item. For K–12 academic assessments, invited panelists are often educators, because they tend to be most familiar with academic content standards, knowledge which is critical for making informed ID Matching judgments (Cizek, 2006; Cizek and Bunch, 2007; Ferrara and Lewis, 2012; Ferrara et al., 2014). In addition, developing preliminary PLDs prior to the standard setting meeting is critical to the success of this method. In most implementations of ID Matching, an OIB is provided to panelists, so that they can consider the relative difficulty of items, as well as the specific item content, when determining the performance level to which an item best aligns (Ferrara and Lewis, 2012).

According to Ferrara and Lewis (2012, p. 263), panelists should consider two questions as they make their item judgments: “What does an examinee need to know and be able to do in order to respond successfully to this item or at this score level?” and “What makes this item more difficult than previous items?” A panelist considers these questions for each item and records a judgment as a performance level. These judgments are often recorded in a table like Table 4, which provides an ordering of the items being reviewed, along with metadata about the items being considered, such as a content standard alignment and item difficulty (Cizek and Bunch, 2007; Ferrara et al., 2014). The final column is initially blank; each panelist uses it to record judgments, which are then used to identify cut scores. In the example in Table 4, the judgments do not move strictly from low to high performance levels (in this case, Basic to Proficient). The ID Matching method allows for reversals in judgments in cases where a panelist thinks that a more difficult item aligns best to a lower performance level. In this example, once the performance level cut score is determined, items below the Proficient performance level cut score will be classified as Basic, while all items above that cut score will be classified as Proficient.

In many implementations of ID Matching, patterns in the panelists’ judgments are considered after the first round. Items on the border of two performance levels—referred to as the threshold region—become the focus of subsequent rounds of review. In the example in Table 4, the threshold region between Basic and Proficient includes items 5 through 10. The Proficient cut score is presumed to be a scale score somewhere between the scale scores of item 5 and item 10.

For the ID Matching method, impact data shared with panelists focuses on the locations at which a cut could be placed in the threshold region, and panelist discussions focus on the match of item content to PLDs within the threshold region. In some implementations of ID Matching, the goal by the end of the standard setting meeting is to determine the item in each threshold region that most closely matches the content of the next performance level. Cut scores are typically determined using logistic regression (Ferrara and Lewis, 2012; Ferrara et al., 2014). However, as described in the following section, a new method that improves on logistic regression has been proposed for locating the cut score.

Embedded standard setting

Embedded Standard Setting (ESS; Lewis and Cook, 2020) coordinates and extends existing assessment development practices such that standard setting becomes a logical extension of assessment design and item development, rather than as a post hoc activity. In the standard implementation of ESS, PLDs are developed prior to both standard setting and item writing, and items are written explicitly to elicit evidence for the PLDs. Judgments of performance level alignment, then, are incorporated into the item-writing process, and cut scores are established empirically, based on the agreement of item-writer judgments and items’ empirical

Table 4 Example ID matching judgment form.

<i>OIB item number</i>	<i>Content standard</i>	<i>Empirical item difficulty (p-value)</i>	<i>Item-descriptor judgment</i>
1	C.2a	0.92	Basic
2	C.1b	0.90	Basic
3	C.1b	0.89	Basic
4	M.2	0.88	Basic
5	C.2c	0.86	Proficient
6	M.1	0.84	Proficient
7	F.6	0.80	Basic
8	B.1a	0.79	Proficient
9	M.1	0.78	Proficient
10	B.2	0.77	Basic
11	F.5a	0.75	Proficient
12	F.3	0.72	Proficient
13	C.1a	0.71	Proficient
14	F.6	0.70	Proficient
15	M.1	0.70	Proficient

difficulties. A key advantage of ESS is that subjective evaluation of item alignment to PLDs by a second set of subject-matter experts is not necessary when there is alignment between item-writer judgments and item difficulty parameters.

Because the first published description of the ESS method came out in 2020, many testing programs implementing ESS at the time of writing this article are doing so “in flight”—that is, after at least some items have been written and field tested—rather than following the “full” ESS protocol (i.e. item-to-PLD alignment judgments are being made as the items are being written, prior to field testing). Furthermore, for some programs, a set of cut scores in a given grade is one part of a larger system of cut scores, where the system is articulated vertically across multiple grades and typically placed on a single underlying vertical scale. Therefore, articulation of cut scores across grade levels must be considered, ideally early in the process.

ESS is particularly helpful for assessment programs that have the time, resources, and discretion to iterate. Every cycle of ESS (writing items aligned to PLDs and then reconciling those alignment judgments with empirical data) will surface misaligned items—for example, items that are judged to align with the lowest placement level but that are among the most difficult in the bank. As long as the field test was robust and the empirical data show no obvious signs of bias, these discrepancies can be corrected through revisions to the PLDs. Within reason, misalignments are therefore useful because they provide an opportunity for the assessment developer to make data-driven adjustments to PLDs.

An additional innovation of ESS is the mechanism for translating ID Matching results into cut scores. Rather than logistic regression, a weighted penalty that minimizes the number of items that fall on the “wrong” side of the cut score, based on expert judgment, is calculated by identifying the cut scores. [Lewis and Cook \(2020\)](#) proposed a method called ESS-Count to optimize cut score placement, and [Lewis et al. \(2021\)](#) introduced an additional cut score placement method, which they called ESS-Weight. Simulations conducted by [Gaertner and Powers \(2021\)](#) indicated that ESS-Weight has better properties for setting cut scores, compared to ESS-Count, and produces superior results compared to logistic regression.

Contrasting groups method

For the Contrasting Groups method, instead of having content experts align items with performance levels, panelists must be familiar enough with examinee ability to classify examinees into performance levels. For example, when examinees are students, the panelists should be teachers who are familiar with students’ knowledge and skills in the subject of interest. The panelists review the PLDs, think about which description best describes a particular student, and provide a judgment for the student. This method requires a sample of students that spans the performance continuum, as well as a sufficient number of panelists who are familiar with the students to provide an informed judgment.

As with ID Matching, Contrasting Groups cut scores are often calculated using logistic regression ([Hambleton and Pitoniak, 2006](#)). However, the newer ESS-Weight method ([Lewis et al., 2021](#)), described in the previous section, can also be used to translate judgments into cut scores.

Body of work method

Many standard setting methods have been developed for use with multiple-choice items. Although some such methods can be modified for use with performance assessments or mixed-format assessments, these methods are often not well suited to such assessments. To address this need, the Body of Work method ([Kingston et al., 2001](#)) was designed especially for performance assessments. As the name suggests, Body of Work is a method in which examinees’ responses to all items on an assessment are provided to panelists. Panelists review all responses systematically to identify the set of scores that constitutes the minimum required knowledge and skill for a particular performance level. Judgments are not made on an item-by-item basis, but are made holistically, taking into consideration examinee performance on all items within the set. This method is often applied to writing assessments, portfolio-based assessments, video-recorded performances, and observation-based assessments.

Many of the steps in the Body of Work method are similar to steps in other standard setting methods (e.g. recruiting panelists, conducting a meeting with multiple rounds). One salient difference is the inclusion of sets of examinee work, which are then classified by panelists as part of the standard setting judgment process. These examinee work samples must be strategically selected prior to the standard setting activity. Prior to selecting examinee work samples, all items must be scored. These scores must be reliable in order to provide useful input to the standard setting method. Thus, examinee responses would ideally be double-scored by trained human raters. Once items for all examinees are scored, a subset of examinees is systematically selected, and these examinees’ responses to all items on the assessment are included in the standard setting meeting. These sets of examinee responses are used for three different purposes: training, range-finding, and pinpointing.

Training

During the training portion of the standard setting meeting, panelists are often asked to perform the standard setting task, using a small “training” set, to get them comfortable with completing the task and entering their judgments into a paper or electronic form. For this task, a small set of examinee assessment responses (“bodies of work”) is needed, such that panelists can independently evaluate the responses and determine which performance level is best aligned with the quality of the responses. This training set is typically not part of the range-finding or pinpointing sets, though it could be a very small subset.

Range-finding

The first round of judgments for the Body of Work method is called range-finding. During this round, panelists review examinee work that spans the full performance continuum. The range-finding activity involves at least one round of independent judgments, but often also includes time for group discussion and for panelists to modify judgments, based on that discussion. The outcome of the range-finding activity is the identification of a narrow region of the score scale associated with each cut score. This region includes examinee work for which there is substantial disagreement among panelists as to the performance level it represents. This type of disagreement is most common at the threshold of a performance level.

Pinpointing

The second round of judgments for the Body of Work method is called pinpointing, because this round focuses on a narrower region of the scale, to home in on the cut scores. Typically, new bodies of work, representing score points close to where the cut score is likely to be, are added in this round. The new examinee work samples are selected prior to the standard setting meeting, so that they are available at the meeting. Because the cut scores are not known ahead of time, facilitators must be prepared with many alternative pinpointing sets. During this round, panelists repeat the process of classifying bodies of work into performance levels. After independent judgments, there is often a group discussion, after which panelists are able to change their judgments if they wish.

Logistic regression is used to calculate the raw score at which point the probability is 0.5 of being in a particular performance level or higher (e.g. “proficient” or higher) versus being in the next lower level (e.g. the category below “proficient”). Using logistic regression, the panelist judgments are converted into a cut score (see [Cizek and Bunch \(2007\)](#) for an in-depth example). After the cut scores are computed, feedback data can be provided. In some applications of the Body of Work method, a third round of judgments is conducted, during which panelists are asked to provide the minimum score that examinees in each performance level should obtain, based on feedback data and final group discussions. This provides a quick and intuitive mechanism for panelists to adjust their final recommendations.

The Body of Work method can be very time consuming, depending on the number of achievement levels and the complexity of examinee performances (e.g. number of item types, number of items, range of rubrics). Ideally, a pilot standard setting study would be conducted before the meeting—even if only with internal staff—to gauge how long the range-finding and pinpointing rounds are expected to take. If necessary to save time, tasks can be strategically split among the standard setting panel. For example, different panelists could focus on different cut scores. Splitting tasks among the panel will require that the panel is of sufficient size so there is a balance between how many days the standard setting meeting will take and how many panelists are needed for the meeting. The Body of Work method is also dependent upon a large pool of examinee responses to select from. A wide range of examinee performance is needed in order to select a good sample for range-finding. Additionally, several examples of examinee work are needed at each score point along the raw score scale in order to be able to successfully pinpoint the cut scores. Furthermore, for panelists to be able to properly identify cut scores, the assessment must not have obvious floor effects, ceiling effects, and/or scoring artifacts that result in gaps in the score scale.

Post-standard setting meeting activities

Vertical articulation

When standards are set across multiple grades and/or subjects—as is often the case for statewide summative assessment programs—an additional check is needed in order to verify that the standards, as a whole, make sense. Two common ways for evaluating the reasonableness of standards are via vertical scales, when they exist, and via impact data. In general, the cut scores should follow a smoothly increasing trajectory across grade levels. The cut scores need not follow a linear trajectory, since growth curves are typically nonlinear, but they should not be erratic or decrease as grade level increases. Likewise, impact data can differ from one grade to the next, but it should not change dramatically without explanation. Although examinee cohorts are known to differ in performance, dramatic differences are not expected when cohorts are large. Similarly, large differences in percent proficient across subject areas are often rightfully viewed with suspicion by stakeholders. The process of smoothing cut scores to achieve coherence is called vertical articulation, or vertical moderation. Vertical articulation can be included as a culminating activity during the standard setting meeting, in which the panelists (or a subset of panelists from each panel) come together to consider the cut scores holistically. In this case, the panelists can recommend changes to result in more consistent patterns across grades, keeping in mind the impact on the level of knowledge and skills that a change would imply and whether such changes have implications for the PLDs. Alternatively, vertical articulation can be completed after the standard setting meeting with the policy group responsible for approving the cut scores.

Whether vertical articulation occurs within the standard setting meeting or not, there will need to be a review of the full set of standards, with consideration to their coherence as a system. This review will occur when the organization responsible for carrying out the standard setting meetings presents the full set of recommended cut scores to those individuals responsible for approving the standards. Although impact data are typically not the focus of a standards-based assessment program, these data are still an important consideration for those who approve the standards. There are often expectations around how many examinees will pass the test and around the consistency of pass rates across grade levels. These expectations may be based on pass rates from a prior assessment program or on messaging about how the new assessment program is supposed to differ from prior assessment programs in terms of rigor.

If other data, beyond impact data, are used as feedback to panelists, this information should be reviewed with the policy group that is responsible for approving the standards. In doing so, consideration of how to present information concisely, limiting the presented information to only those pieces that are most relevant for decision-makers, is important. When the policy group has been engaged throughout the process, and when its priorities have been embedded into the standard setting process, it is not uncommon for the recommended cut scores that come out of a standard setting meeting to be accepted, or accepted with minor modifications. When this group has not been consulted, or when its priorities have not been emphasized in the design and implementation of the panel meetings, the recommendations are often heavily modified before final cut scores are approved.

Cut score approval and final PLD revisions

Once the cut scores are approved, those leading the standard setting process should complete a final review of the PLDs, especially if the final approved cut scores differed from the recommended cut scores. The final PLDs should reflect what examinees in a performance level actually know and can do, as opposed to what they should know and be able to do. These final PLDs are used to develop reporting PLDs to help test-score users understand the meaning of the performance levels. Therefore, reporting PLDs are empirical in nature, and they are often validated using item mapping methods where IRT is used to determine each item's location on the underlying scale. Item mapping clarifies which skills are represented within each performance level.

Technical report and ongoing validation

After the cut scores are approved, the standard setting process, as well as the final approved cut scores and PLDs, should be documented in a technical report. The technical report should summarize the standard setting method, describe the panelists, provide information about judgments and feedback data from each round, and provide results from panelist surveys (see [Cizek \(2012a\)](#) for examples of panelist surveys). Evidence of internal consistency, external consistency, and procedural validity should be provided to support the standard setting results ([Kane, 2001](#)). Finalized sets of reporting PLDs and cut scores are provided to those responsible for reporting results and included in the technical report. The percentage of examinees classified into each performance level, based on the cut scores, should be monitored over time, and additional external validity evidence should be collected periodically.

Conclusion

Although policymakers, educators, and the public may not be familiar with the details of how standard setting is carried out, the results of standard setting matter for individuals and for institutions. The percentage of examinees scoring at or above a "proficient" level, for instance, is an important part of most state accountability policies for K–12 schools. Similarly, for students, scoring below "proficient" may mean summer school, and for examinees looking to begin a career, it may mean failure to receive a license. Ensuring that assessment cut scores are determined in an accurate, transparent, and fair manner is critical to high-stakes decision-making. Ongoing research extending the "art and science" ([Cizek, 2001](#)) of standard setting is leading to improvements in the process, a better understanding of the strengths and shortcomings of various methods, and, ultimately, assessment information that improves the validity of score interpretations for examinees and other test-score users.

Acknowledgment

Our coauthor, colleague, and dear friend Matthew Gaertner inspired us and many others with his brilliance, wit, and passion. Our time with Matt was cut far too short, but we are honored to have known him, proud to have been part of his team at WestEd, and privileged to carry on his legacy and vision through this book article.

Introduction

Achievement growth modeling is the process of summarizing student achievement for students or groups of students, typically corresponding to teachers, schools, or districts, across multiple timepoints. Achievement growth is often contrasted with achievement status, that is, the achievement of a student or group at a single timepoint. Achievement growth is also distinct from within-grade change over time, which focuses on a specified grade-level or age, and uses multiple cohorts to study change in achievement across multiple timepoints. This entry focuses on achievement growth modeling in state accountability systems in the United States, which have been widely adopted to comply with various state and federal policies.

There are numerous approaches to achievement growth modeling, which can differ in important respects. For example, models can differ in whether growth is characterized in absolute or relative terms, and whether the target of inference is the individual or group. Growth models can also differ in other ways, including the types and features of data that are required, underlying technical properties and statistical assumptions, complexity of the modeling approach, and interpretability of the results. Finally, most growth models can be used to characterize growth in multiple ways, for example, by describing observed growth, or by determining the growth needed to meet a future target level of performance.

At the same time, states vary in their practical and technical considerations with respect to achievement growth modeling. Practical considerations include the intended use of the growth model (e.g., reporting individual student growth, supporting school accountability), the ease with which the model and results can be communicated to stakeholders, and whether the growth model satisfies any policy requirements. Technical considerations include the capacity of the state's longitudinal data system (e.g., what data are collected and stored each year), the degree to which these data support technical properties of growth models, and the testing program's analytical capabilities.

Each state is motivated to select a modeling approach that yields results that are reliable and valid for their intended uses. There are several practical and statistical considerations that factor into selecting a growth model (D'Brot, 2017). However, because each state has unique practical and technical considerations, no single growth model can be considered a gold-standard for all settings. Instead, each model will have a mix of more and less desirable features depending on the context. Consequently, some states use different models for different purposes, for instance, to report individual student growth, and to support school accountability. For these reasons, there is great variety in achievement growth modeling across the states, especially in the details of the methodologies.

The remainder of this entry is organized as follows. First, a brief historical and policy background of growth modeling is provided. Next, several models and their major features are presented. Finally, some relevant statistical properties of achievement growth measures, notably measurement error, are discussed.

Historical and policy background

In the field of educational measurement, achievement growth modeling has been studied since the 1950s, focusing on measuring growth for individual students. Through the 1970s, much of the research concerned the simple gain score (a current score minus a prior score) or residual gain score (a current score minus a predicted current score), measures designed to quantify individual growth or learning (e.g., Cronbach and Furby, 1970; Lord, 1956; McNemar, 1958; Rogosa et al., 1982; Traub, 1967). Measurement properties of these scores, in particular the reliability of gain scores, received a great deal of attention.

In the 1980s, more sophisticated approaches to modeling growth, such as the use of hierarchical linear modeling, began to appear in the literature (e.g., Bryk and Raudenbush, 1987; Rogosa and Willett, 1985). Notably, some of these approaches integrated background variables to directly model correlates of change (i.e., the relationship between background variables and individual growth). Such approaches could be used to study questions such as “What kinds of persons grow (learn) fastest?” (Cronbach and Furby, 1970, p. 77). From a historical perspective, these approaches can also be understood as precursors to value added modeling (Sanders and Horn, 1998; McCaffrey et al., 2004), which aims to isolate the contribution of individual teachers and schools to student growth.

Around this period, using test scores for accountability purposes became more common. Though testing for accountability has a long history in the United States (Shepard, 2008), the 1980s and 1990s saw state and federal policies, such as the Improving America’s School Act of 1994 and the No Child Left Behind Act (NCLB) of 2001, encouraging more comprehensive accountability systems. Initially, most accountability efforts focused on achievement status, in contrast to growth, using the current year’s student achievement to make judgments about the quality of education provided by teachers, schools, districts, and states (Shepard, 2008). For example, under NCLB, states were required to publicly report proficiency rates for all students, as well as select subgroups of students, within a school. States then used these rates to compare schools and districts, and to evaluate effectiveness.

Since the 2000s, researchers and policymakers have increasingly recognized that such status-based accountability systems may not capture the contributions of teachers and schools to students’ academic progress or growth (Linn, 2003). For example, such systems may fail to recognize effective teachers and schools that tend to serve students with low initial achievement levels, as well as ineffective teachers and schools that tend to serve students with high initial achievement levels. In contrast, growth measures are more closely tied to a student’s learning or individual progress, and are typically viewed as being more equitable than status measures (Linn, 2008). Thus, coupled with status measures, growth measures provide stakeholders with more complete pictures of student learning.

Recent federal and state policies and programs reflect this recognition of the importance of growth measures. Examples include the Growth Model Pilot Program of 2005, Race to the Top competitive grant program of 2009, and Elementary and Secondary Education Act (ESEA) flexibility waivers (2012), all of which incentivized states to adopt student growth measures. Also, the Every Student Succeeds Act of 2015, the current reauthorization of the ESEA, encourages state adoption of growth measures, mandating that state assessment systems must include multiple indicators of school quality and student success. Under ESSA, for elementary and secondary schools, states must include a student growth measure, or another valid and reliable indicator, that supports meaningful differentiation in student performance.

Achievement growth models

The purpose of this section is to provide an overview of common achievement growth models. We classify the models into one of four general approaches: gain score, categorical, student growth percentile, and value-added model. Though other classifications of the models are possible (Castellano and Ho, 2013; Goldschmidt et al., 2012; Martineau, 2016), we believe the proposed groupings, adapted from those proposed by Domaleski and Hall (2016), are conducive to covering the approaches used by most states.

The presentation for each model is organized around four topics. The first topic is a model overview. This includes the primary question the model is designed to answer, with respect to characterizing observed achievement growth. It also covers other fundamental features, such as whether the model characterizes growth in absolute or relative terms, and whether it yields individual or group-level growth estimates. When applicable, the overview also includes how the model may be used to determine the growth needed to meet a future target performance level, which we refer to as “growth to standard” (Domaleski and Hall, 2016). Also, where feasible, the overview includes a brief numerical example. Finally, examples of recent operational uses are provided.

The second topic is modeling requirements. In general, achievement growth modeling results must satisfy typical validity and reliability standards to justify their use (American Educational Research Association et al., 2014). Note that the results may be used for a variety of purposes (e.g., describing student growth, aiding in teacher or school evaluation), and the validity and reliability of each of these uses could be studied separately (e.g., Castellano and McCaffrey, 2020a,b; Hill, 2009). In general, however, the validity and reliability of growth measures relies, in part, on the extent that modeling requirements are met. To this end, we present

modeling requirements specific to the growth models, such as a vertical scale and cut scores articulated across grades. General issues of reliability will be discussed in a separate section, “Statistical Properties of Achievement Growth Measures.”

The third topic is determining growth adequacy. For reporting and accountability, stakeholders are often interested in determining whether growth is “adequate,” at both the individual and group levels. The possible ways in which growth standards may be set, however, depends on the specific growth model. To clarify these issues, for each model, we discuss how individual growth measures can be aggregated, and how growth adequacy determinations can be made.

The fourth and final topic is model advantages and disadvantages. Here, we present some of the more notable benefits and drawbacks for each model.

The gain score model

Model overview

Gain scores are arguably the most intuitive growth measure and characterize observed student growth in absolute terms. They are designed to address the question, “What is the magnitude of student growth?” A straightforward answer to this question is the gain score, defined as $G = X_2 - X_1$, where X_1 and X_2 are the student’s test scores at times 1 and 2, respectively (Lord and Novick, 1968). As an example, suppose a student has mathematics test scores of 400 in grade 3 and 450 in grade 4. Then, the corresponding gain score is simply $50 = 450 - 400$, indicating a 50-point increase or improvement. Gain scores have a long history in educational measurement (e.g., Lord, 1956), and have seen recent operational use in states such as Alabama (Alabama Department of Education, 2019) and Texas (Texas Education Agency, 2018).

Gain scores may also serve as the basis of a growth-to-standard measure. Two preliminary steps in calculating growth to standard are specifying a future target grade and a target performance level. Returning to our example student, assume these targets are grade 6 and the Proficient performance level, respectively. Further, assume the corresponding cut score is 490. Then, using the gain score model, the annual target growth needed by our student to progress from the initial grade 3 score of 400 to a grade 6 target score of 490 is $30 = (490 - 400)/3$. This growth-to-standard measure based on gain scores is sometimes referred to as the “trajectory model,” and has seen recent use in Connecticut (Connecticut State Department of Education, 2017) and Idaho (Idaho State Board of Education, 2018).

Modeling requirements

A requirement for gain scores to be meaningful is that the two test scores must be on a common interval scale. In a conventional pretest-posttest design, this requirement is satisfied if the same test or parallel forms of the same test are used at the two timepoints. When the two tests are different (as with the example mathematics tests in grades 3 and 4), this requirement can be satisfied through vertical scaling, a process used to place scores onto a common scale when tests measure similar domains, but at different grade levels (Kolen and Brennan, 2004). Vertical scaling is a complex endeavor that incorporates several psychometric tasks, including selecting measurement models and scaling procedures, linking, and standard setting (Dorans and Moses, this volume; Patz, 2007).

For the growth-to-standard approach of the trajectory model, the vertical scale requirement is more stringent, because the studied grade span is greater. That is, the simple gain score model assumes that properties of the vertical scale hold for 2 years, whereas the extended trajectory model assumes the properties hold for the entire studied grade span (e.g., grades 3 through 6 for the example student).

In addition, as used in practice, the trajectory model requires that cut scores across grades be articulated (Cizek, 2005). This means that performance levels across grades should have the same meaning and rigor, and that performance level classification rates for adjacent grades should be similar. These cut score characteristics facilitate cross-grade comparisons, and without them, predicting future proficiency is less sensible. For example, if cut scores substantially vary in stringency across years, then the percentage of students who are “on track” will be overly dependent on the choice of target year.

Determining growth adequacy

Determining adequate growth for students based on gain scores is usually done in one of two ways. First, standards can be set on the gain score scale, which corresponds to the underlying vertical scale. For example, a state may use the difference in performance level cut scores in consecutive grades to define adequate growth. If, for instance, the cut scores for the Basic performance level in grades 3 and 4 are 400 and 430, respectively, then under this approach, $G \geq 30$ may represent adequate growth. Second, standards can be norm-referenced, based on percentile ranks of gain scores in a reference group, such as all students in the same grade and subject in a given district. For example, a percentile rank of at least 50 may represent adequate growth.

Similarly, determining adequate growth for students using the growth-to-standard trajectory model is usually carried out in one of two ways. The first approach simply compares the student’s observed growth to the target growth, yielding a yes/no determination of whether the student is “on track.” Returning to the example, the student is deemed “on track” because the student’s observed growth (50) exceeds the growth target (30). This “on track” determination can be made another way with equivalent results, by comparing the target score of interest to the student’s projected score found by extrapolating their current gain. Assuming constant gains, the student’s projected grade 6 score is $550 = 450 + 2 \times 50$. Because the student’s projected grade 6 score (550) is greater than the target cut score (490), the student is deemed “on track.” The second approach also compares the observed growth and target growth, but uses an achieved percentage of the target growth. For the example student with observed growth of 50 and target growth of 30, this achieved percentage is $167\% = 50 \div 30$. Note that any percentage greater than 100 corresponds to “on track.”

To facilitate group-level reporting based on gain scores, the gain scores for students within the group are often averaged. As with individual student gain scores, standards for adequate average group gains can be set on the gain score scale or norm-referenced. Alternatively, the student-level classifications of adequate growth can be aggregated to produce a group-level statistic, the proportion of students exhibiting adequate growth.

Group-level growth adequacy under the growth-to-standard extension of the gain score model (i.e., the trajectory model) can also be determined in several ways. First, projected scores within a group can be averaged, and this average can be compared to a target score (e.g., the cut score for Proficiency). Second, if achieved percentages are used, then these can be averaged and compared to some standard, such as 100%. Finally, as with the gain score model, the proportion of students exhibiting adequate growth may be used.

Advantages and disadvantages

Gain scores and the related growth-to-standard measures have numerous strengths. Due to their simplicity and clear connection to achievement scores, they are straightforward to understand, explain, and calculate. Arguably, they are easy to interpret, because they are on the same scale as the underlying test scores. Also, much is known about the measurement properties of gain scores because educational researchers have been studying them for decades (e.g., Lord, 1956). A strength specific to the growth-to-standard measure is that there is no need to set scale-based standards, as it relies on existing cut scores.

At the same time, these gain score measures have several notable weaknesses. First, they require a vertical scale, and therefore the model is not a viable choice for some states. Second, the accuracy and meaningfulness of these measures depends on the soundness of the underlying vertical scale and, in the case of the growth-to-standard measure, articulated cut scores. To the extent that the vertical scale or cut scores are poorly developed or maintained, the justification for typical uses and interpretations of these growth measures may be threatened (Tong and Kolen, 2007). For example, the vertical scale could exhibit floor or ceiling effects, or initial status could be related to the gain scores. Third, direct comparisons of gain scores can be challenging. Vertical scales are designed to facilitate direct comparisons of test scores across grades. However, depending on properties of the scale, typical gain scores may differ by grade. A fourth weakness, touched on above, is that raw gain scores are hard to interpret without a corresponding growth category (e.g., “high”).

The categorical model

Model overview

The categorical model (also referred to as the value table or transition model) is similar to the gain score model and characterizes observed student growth as transitions across performance levels over time. The categorical model aims to address the question, “How has the student grown in terms of performance level classifications?” To illustrate the categorical model, assume that the following ordered performance level categories are used for each grade: Below Basic, Basic, Proficient, and Advanced. These levels are mapped to the test scale using cut scores. Then, to characterize observed growth, all of the possible combinations of levels for the prior and current grades can be represented in a transition matrix, as shown in Table 1.

Table 1 shows how the possible combinations correspond to positive growth, no growth, or negative growth, with respect to the performance levels. Returning to the example student with test scores of 400 and 450 in grades 3 and 4, assume these scores correspond to performance levels of Basic for the prior grade and Proficient for the current grade, respectively. Then, the categorical model would describe this student’s performance as positive growth of one level. The categorical model has recently seen operational use in states such as Florida (Florida Department of Education, 2018) and Virginia (Virginia Board of Education, 2018).

The categorical model may also be used as the basis for a growth-to-standard measure, much like the trajectory model. Whereas the categorical model characterizes observed growth by considering all combinations of prior and current performance levels (as in Table 1), the growth-to-standard approach considers all possible combinations of current and projected performance levels. The result is a transition matrix identical in structure to Table 1, but based on current and projected performance levels. A student’s

Table 1 Example transition matrix.

Prior grade performance levels	Current grade performance levels			
	Below basic	Basic	Proficient	Advanced
Below basic	0	1	2	3
Basic	−1	0	1	2
Proficient	−2	−1	0	1
Advanced	−3	−2	−1	0

Note. Entries indicate the direction (positive or negative) and number of performance levels of growth in the transition. For a growth-to-standard approach, “Prior Grade” and “Current Grade” are replaced by “Current Grade” and “Projected Grade,” respectively.

projected performance level is found by classifying the student's projected scale score in the target year, which can be found using various approaches (e.g., assuming constant gains). A recent proposal by Kentucky ([Kentucky Department of Education, 2018](#)) provides an example of this growth-to-standard measure based on the categorical model.

Modeling requirements

The categorical model requires a vertical scale and articulated performance levels. In some cases, the original set of performance levels, used to describe achievement, is further divided into sublevels, creating additional combinations of levels to characterize growth. For example, the Basic level may be split into Basic-1 and Basic-2 levels. An advantage of this practice is that it has the potential to provide more detailed descriptions of growth. Increasing the number of performance levels, however, introduces additional demands. First, with this practice, the task of creating articulated performance levels across grades becomes more challenging. And second, the underlying achievement scores must be sufficiently precise to support finer-grained descriptions of growth (e.g., [Lee, 2010](#)).

Determining growth adequacy

The categorical model provides a flexible framework for defining growth adequacy at the student and group levels. In general, these approaches depend on a Value Table, which assigns numerical values to all possible transitions. A Value Table can be based on the number of performance levels of growth, as in [Table 1](#), but can also be constructed to reflect more nuanced valuations of growth. For example, in [Table 2](#), students who transition zero performance levels are assigned different values depending on the student's initial performance level. For instance, students maintaining Proficiency each year are assigned more points than those maintaining the Basic level each year.

At the student level, standards can be set for which transitions constitute adequate growth. For example, using [Table 2](#), perhaps all values of 50 or more are deemed adequate growth. The group level calculations can be made in one of two ways. One possibility is to aggregate the student level determinations, resulting in a percentage of students with adequate growth that can be compared to some benchmark (e.g., 50%). A second possibility is to find the average transition value. In this case, a standard is set for the average transition value (e.g., 100). Note that all of the approaches can be used with the growth-to-standard version of the categorical model as well.

Advantages and disadvantages

A notable strength of the categorical model is its clear connection to performance levels, which facilitates communication with various stakeholders. Student and group-level results are also easy to calculate. Another strength is the flexibility afforded by using value tables; these tables can clarify how states value different types of transitions.

The categorical model also has a few weaknesses. Like the trajectory model, the categorical model has stringent modeling requirements, particularly when it is used to project future performance levels. Another weakness is that the coarse nature of the transition categories can obscure variability in underlying gain scores, sometimes with counter-intuitive results. For example, consider two students with the same raw gain score G , but different initial scores. Depending on the locations of the cut scores, the students may have unequal growth transitions. This weakness may be alleviated by subdividing the original performance levels. However, such splitting of levels may not involve a typical systematic standard setting process, which can complicate the interpretation of the sublevels. Finally, the categorical model is not well-suited for students scoring at extreme performance levels. For example, it is unclear what should count as adequate growth when the initial score is classified as Advanced.

The student growth percentile model

Model overview

In its most basic form, the Student Growth Percentile (SGP, [Betebenner, 2009](#)) model is used to characterize observed student growth in normative terms. Though there are different implementations, in general, the model is designed to answer the question, "How does the student's current performance compare to those students with similar score histories?" This is the same question addressed by the residual gain score model, which was of historical interest (e.g., [Cronbach and Furby, 1970](#)) as well as in use by some states (e.g., [California Department of Education, 2021](#)). A detailed description of how SGPs are estimated is beyond

Table 2 Example value table.

Grade 3 performance levels	Grade 4 performance levels			
	Below basic	Basic	Proficient	Advanced
Below basic	0	100	150	150
Basic	0	50	125	125
Proficient	0	0	100	100
Advanced	0	0	100	100

the scope of this entry. However, assume that the scores of 400 in grade 3 and 450 in grade 4 for our example student result in an SGP of 75. The SGP model supports the interpretation that the student's growth was greater than approximately 75% of students with similar starting points (i.e., grade 3 scores near 400). The SGP model has recently seen operational use in states such as New York ([New York State Education Department, 2018](#)) and Oregon ([Oregon Department of Education, 2017](#)).

As with the gain score and categorical models, the SGP model can be extended to create a growth-to-standard measure. Once the target year and performance level have been identified, the SGP model can be used to find the target growth (i.e., target SGP) needed to progress from the initial score to the target score (e.g., the cut score for the target performance level). Returning to our example, recall that the student's grade 3 score is 400. Again, assume the target year and performance level are grade 6 and Proficient, respectively. Then, the SGP model can be used to find the corresponding target SGP, which, for illustrative purposes, we assume is 40. The interpretation is that for the student to progress from the initial score to the target score the student needs a minimum SGP of 40 over the next 3 years. This target SGP is sometimes referred to as an adequate growth percentile (AGP). The AGP growth-to-standard measure has seen operational use in [Colorado Department of Education \(2018\)](#) and [Michigan Department of Education \(2017\)](#).

Modeling requirements

In contrast to the gain score-based methods discussed thus far, SGP models are relatively complex statistical models that can require specialized software, such as the [R Core Team \(2019\)](#) package SGP ([Betebenner et al., 2021](#)). Unlike the gain score-based methods, SGP models do not require a vertical scale. The original implementation ([Betebenner, 2009](#)), which is also the most widely used, depends on a sophisticated and flexible type of regression modeling, known as quantile regression. This approach to SGPs does not require linearity between past and current scores, and does not assume homoskedastic errors. These features increase the flexibility of the approach to fit a wider range of data, but also increase the need for a large sample size. Readers interested in greater technical detail of this approach are referred to [Betebenner \(2009\)](#) and [Betebenner et al. \(2021\)](#). Alternative approaches to SGPs rely on ordinary linear regression ([Castellano and Ho, 2013](#)), which has stricter modeling requirements, but is likely to perform better when sample sizes are smaller. SGP model implementations can also differ in how measurement error in the achievement scores is handled ([Shang et al., 2015](#)).

Determining growth adequacy

At the student level, determining adequate growth can proceed in two ways. The first approach depends solely on observed growth, and sets a standard for the observed SGP. For example, SGPs of at least 50 could be deemed to reflect adequate growth. The second approach simply compares the observed SGP with the student's AGP. If the SGP exceeds the AGP, the student's growth is deemed sufficient—the student is “on track.” As with the trajectory model, alternatively, but equivalently, the student's projected score assuming constant growth (SGP) over time can be found and compared to the target score; if the projected score exceeds the target score, the growth is deemed sufficient or the student “on track.”

To summarize student level growth, SGPs and AGPs are typically aggregated using the mean or median. Alternatively, the percentage of students demonstrating adequate growth can be used. Standards can then be set for these aggregate measures, or they can be compared normatively.

Advantages and disadvantages

A major advantage of SGPs is that they are relatively easy to interpret. An SGP of 75 has the same interpretation, regardless of the underlying score scale or performance levels. Also, an intuitive reference of typical growth, an SGP of 50, is built into the measure. A final advantage is that SGPs do not require a vertical scale.

SGPs, however, also have several weaknesses. First, they require large sample sizes, and even then, SGPs for students with outlier scores can be somewhat unstable. Second, compared to the simpler gain score-based models, the SGP model is more complex to implement although they can be computed with the SGP ([Betebenner et al., 2021](#)) package in [R Core Team \(2019\)](#). Finally, the SGP model, in its most basic form, does not communicate any information about performance levels.

The value-added model

Model overview

Value-added models are used to characterize the contributions of individual teachers, schools, or districts to student achievement, in normative terms. These models are designed to answer the question: “How does the performance for a group of students compare to expectations?” For the simplest approach, expectations depend on students' test scores for the prior year in the same subject. For more complex approaches, such as the popular Educational Value-Added Assessment System (EVAAS) ([Sanders and Horn, 1998](#)) model, expectations may also depend on students' scores in other grades and subjects, students' teachers in other grades and subjects, and average district scores for each grade and subject. Expectations may also depend on student background covariates and classroom aggregates of such covariates. Conceptually, the difference between the expectations and the observed student scores are then attributed to the teacher (or school, depending on the level of interest). These attributions are referred to as effects (e.g., teacher effects), and are relative to those of the average group for the population (e.g., the average teacher within a district). As with SGPs, a more detailed description of how teacher effects are estimated is beyond the scope of this entry (see [Broatch et al., this volume](#); [Koedel et al., 2015](#)). In practice, value-added models are most useful for identifying teachers with especially high or low effect estimates, as opposed to producing precise rankings of the estimates ([Lockwood et al., 2002](#)).

Because value added models have been used for high-stakes decisions within accountability systems, the appropriate use of value-added models and interpretations of results has proven controversial (e.g., [Baker et al., 2013](#)). There is sometimes a tendency to interpret these results as authoritative indicators of teacher effectiveness, perhaps because value-added model results are obtained using sophisticated statistical models and standardized test scores. However, more careful, qualified interpretations are appropriate for several reasons ([Morganstein and Wasserstein, 2014](#)). For example, because value-added models operationalize teacher effectiveness in terms of standardized test scores, they do not directly reflect other dimensions of teacher effectiveness. Another example is that value-added model estimates may be biased (e.g., undervalue some teachers) when background variables related to classroom-level differences are not included in the model ([McCaffrey et al., 2004](#)). Value-added models have seen recent use in numerous states including Ohio ([Ohio Department of Education, 2018](#)) and Tennessee ([Tennessee Department of Education, 2018](#)).

Modeling requirements

Like the SGP model, value-added models are relatively complex statistical models. Most value-added models, including the EVAAS model, are linear mixed models, designed for analyzing hierarchical data ([SAS, 2021](#)). This modeling framework is flexible, and value-added models can differ in several respects, including how many years of test scores are analyzed, and which background variables are included. Unlike the SGP model, value added models explicitly incorporate group membership variables, which correspond to the estimated teacher effects. For most forms of value-added modeling, a vertical scale is not required. Among the growth models covered in this entry, value-added models place the greatest demands on the underlying longitudinal data system. For example, for the EVAAS model, the data system must track students, and their teachers, schools, and districts for each year included in the analysis. Finally, value-added models require large numbers of students per teacher for more precise teacher effect estimates.

Determining growth adequacy

Unlike the other growth models covered in this entry, value-added models are not typically used to obtain student-level growth results. Instead, the teacher (or school or principal) is the focus of the analysis. Standards can be set by classifying a top or bottom percentage of teachers, or by classifying teachers with effect estimates different than a cut-score, using the standard error of measurement.

Advantages and disadvantages

One advantage of value-added models is that many factors believed to influence achievement and growth can be included in the model, and used to adjust expectations. Two other advantages, owing to the modeling framework, are that value added models can accommodate missing data, and that no vertical scale is required. A final advantage of value-added models is that they have received a great deal of attention from researchers (e.g., [Ballou et al., 2004](#); [Chetty et al., 2014](#); [Papay, 2011](#)).

Value added models also have weaknesses. They are complex to implement, as they require large samples, sophisticated longitudinal data systems, specialized software, and considerable statistical expertise. Also, like SGPs, though teacher effects can be explained at a conceptual level fairly easily, it is often challenging to provide a detailed, transparent explanation of the methodology. A final weakness of value-added models is that they are often not designed to produce student level growth results.

Statistical properties of achievement growth measures

This section covers some of the statistical properties and concerns of achievement growth measures. Though these topics are more technical in nature, their inclusion in this entry are important because the utility of growth measures can depend on, or be limited by, statistical properties. Before discussing growth measures, we discuss some aspects of achievement tests (i.e., status measures) and their development, as they provide useful points of comparison. Also, this section focuses on properties of student growth measures, though aggregated growth measures are also briefly discussed.

Design and development of achievement tests for state accountability systems is a complex endeavor, and includes the development of psychometric and scoring specifications. An important psychometric consideration is test precision, which refers to the consistency of the scores across testing occasions. In general, measurement frameworks (e.g., classical test theory) assume that examinee's scores are inconsistent from one testing occasion to another due to measurement error. And regardless of the measurement framework, the observed score, say X , is considered just an estimate of the true or latent score, say T . Notably, test precision can be improved, for example, by adjusting the test length. As such, state tests are designed to have relatively high precision, with reliabilities typically around 0.9 ([Castellano and McCaffrey, 2020a](#)), which facilitates meaningful score reporting.

An important scoring consideration for achievement tests is determining how scores X will be calculated, for example, using sum scores or IRT-based maximum likelihood scoring. Due to decades of study, the properties of popular scoring methods for estimating the latent score T are well-known. A related question is how to communicate the precision of X in score reporting, such as with confidence intervals or conditional standard errors of measurement.

Reviewing these topics as they relate to growth measures reveals some limitations of the methodology and concerns with how growth modeling is used in practice. One limitation of the methodology is that there is general consensus that in the context of state summative testing, individual-level growth measures are substantially less precise than the achievement scores on which they depend ([Castellano and McCaffrey, 2020a](#); [McCaffrey et al., 2015](#); [Monroe and Cai, 2015](#)). This phenomenon is primarily due

to the high correlation of achievement scores across years (McCaffrey et al., 2015, p. 20) and affects all popular growth measures. Unfortunately, this means that it is impractical to improve the precision of individual-level growth measures (e.g., by substantially increasing the length of summative assessments), so long as they are based on conventional achievement tests.

A second limitation is that compared to established methods for scoring achievement tests, less is known about properties of methods for calculating growth, for several reasons. One issue is that the methods themselves (e.g., SGPs) are relatively new, and thus have been studied less. Another issue is that in contrast to conventional test scoring, there are a greater number of approaches to producing growth scores. Even with one approach (e.g., value added modeling), implementations can differ in important respects that affect statistical properties. A final issue is that with growth measures, there are arguably more statistical properties that should be evaluated. One important example is whether the growth estimates exhibit systematic bias, such as whether overestimation or underestimation of true growth depends on prior achievement (McCaffrey et al., 2015; Shang et al., 2015).

Turning to concerns with how growth modeling is used in practice, one shortcoming is that it is sometimes unclear how latent growth is being defined. However, such definitions are critical for evaluating psychometric properties of growth measures, such as precision and bias (Lord, 1958; McCaffrey et al., 2015; Shang et al., 2015).

A related concern is that in score reporting, the precision of growth score estimates or classifications is typically ignored. Excluding this information, however, makes it more difficult for students, parents, and teachers to fairly evaluate student learning. As noted above, in contrast, achievement scores are typically reported with accompanying measures of uncertainty, in accordance with Standard 2.14 of the *Standards for Educational and Psychological Testing* (American Educational Research Association et al., 2014).

Some, but not all, of these limitations and concerns extend to aggregate growth measures, including concerns with systematic bias (McCaffrey et al., 2015; Shang et al., 2015). One important difference is that aggregate growth measures, such as means, tend to have greater precision than individual growth measures. A notable complication for aggregate growth modeling, however, is student sorting, that is, the systematic difference between classes in terms of student characteristics (Castellano and McCaffrey, 2017, 2020b; Shang et al., 2015).

Glossary

Bias The expected value of the difference between a statistical estimator and the quantity that is being estimated

Fixed effects Terms included as explicit explanatory variables in linear models in which model parameters are estimated via least squares or maximum likelihood methods. Typically used to refer to models that include indicator variables for individual units such as schools, teachers, or students

Longitudinal data Data from multiple units with repeated measurement on one or more units over time.

Precision The reciprocal of the sampling variance of a statistical estimator

Random effects Term included in statistical models that are latent and assumed to be random variables from a common distribution

Value-Added Models (VAMs) are methods used in education to estimate contributions of individual teachers, or other educational inputs, toward student achievement. Broadly speaking, VAMs attempt to estimate the “value added” on student achievement by a teacher or other educational input, while controlling for other factors, such as baseline student and classroom performance and characteristics (prior achievement, student/family background, school demographics).

VAMs, which were originally introduced in economics literature on the contribution of current inputs or processes to an output after accounting for previous inputs, have become a popular educational measurement tool. In response to the Race to the Top Act of 2009 (U.S. Department of Education, 2016), almost all states adopted teacher accountability systems that utilized VAMs; VAMs’ claimed ability to isolate a teacher’s effect while controlling for a student’s background made them attractive for measuring teacher effectiveness. Although the Every Student Succeeds Act (2015) has recently lessened the required dependence on VAMs for high-stakes accountability policies, VAMs continue to be used across the country as a part of teacher evaluation. VAMs are also used to evaluate school performance and assess the value of educational interventions or programs (Raudenbush and Wilms, 1995).

Studies have shown that high student achievement and highly effective teachers, as measured by VAMs, have been linked to improved life-long outcomes, such as income and educational attainment (Chetty et al., 2014b). Yet, much controversy and discussion surround the use of VAMs in high-stakes evaluation decisions. Although the goal of value-added modeling is to understand how a teacher or another educational input changes student achievement relative to other teachers, most educational settings are not conducive to being able to make causal interpretations of estimated teacher effects (Rothstein, 2009).

☆ *Change History:* Broatch, Manski and Green updated the text and further reading for the entire article.

This article provides an overview of VAMs, along with their limitations and the concerns about their use for high-stakes evaluation. In the following sections, we describe features of the value-added approach and present different types of VAMs that are commonly used in education. Then we discuss several limitations and concerns regarding the use and application of VAMs within education, including bias, stability, and precision of estimates. Although this article focuses on estimating value-added teacher effects, the models, limitations, and discussions presented similarly apply to estimating the effect of other educational factors, such as schools and programs.

Features of the value-added approach

The primary advantage of VAMs compared to other measures used for accountability is their explicit accounting for competing inputs when estimating teacher or school effects. Other accountability metrics—such as comparing schools on average student scores or the percentage of students who surpass an achievement threshold (e.g., the percentage proficient)—typically make no distinctions between appropriated effects of schools and teachers and differences in other inputs that might exist between students in different schools or classrooms. In a VAM, the difference between the student's potential outcome with their assigned teacher and their potential outcome with a different teacher is the effect of the assigned teacher for that student relative to the other teacher. Given that the goal of a VAM is to compare the performance of many teachers, a relevant teacher-level effect is the difference between a student's potential outcome for their assigned teacher and the average of their potential outcomes for all teachers. The average of these teacher-level effects for individual students equals the teacher's overall effect; this average can be over all students in the population or only the students in or likely to be in a teacher's class. In practice, the estimated teacher-level effects are often considered causal effects. However, the claim that the teacher effects are causal effects depends on the random assignment of students to teachers, which is not feasible in a typical educational setting.

Many of the leading value-added modeling approaches, presented in this article, control for the potential differences in schools or teachers by including prior achievement scores rather than simply using demographic or other broad descriptors of students. By incorporating prior achievement, VAMs place greater emphasis on measuring the inputs of schools and teachers and do so more effectively, but not without their own limitations as discussed in the remainder of this article.

Leading value-added modeling approaches

There are many variations of VAMs. This section describes representative examples of the econometric, statistical, and alternative approaches to value-added modeling and their essential features.

Econometric models

The econometric modeling approach to value-added modeling emerged from the cumulative achievement model. The model starts with a general education production function for student achievement:

$$A_{it} = A_t[F_i(t), E_i(t), \mu_{i0}, \varepsilon_{it}] \quad (1)$$

where A_{it} , individual i 's achievement level at the end of the t th year of schooling, depends on the cumulative achievement function A_t and the entire input histories of family (including neighborhood), $F_i(t)$, and school-based educational inputs, $E_i(t)$, a composite variable representing time-invariant characteristics an individual is endowed with at birth (such as innate ability), μ_{i0} , and a normally distributed, mean-zero error, ε_{it} .

Economists make a series of assumptions to specify model (1) in a form that supports estimation of teacher effects using established estimators. In particular, they assume: the cumulative achievement function A_t does not depend on age and is additively separable (i.e., cumulative achievement equals the sum of the effects of the component inputs, and the effect of any one input does not depend on the levels of the others); family inputs are time-invariant and can be combined into a single term with student inputs; and educational inputs can be separated into additive annual contributions of schools, teachers, peers and other classroom inputs (Todd and Wolpin, 2003). Without further assumptions, estimation of the value added of the current teacher would require data on the school, teacher, peer, and classroom inputs for each student's current and entire prior schooling experience. Because these data do not exist, economists typically assume that all educational inputs decay geometrically at a rate λ and that the family inputs change at that same rate, yielding the following model:

$$A_{it} = \gamma_s S_{it} + \gamma_T T_{it} + \gamma_P P_{it} + \gamma_C Z_{it} + \phi_i + \lambda A_{it-1} + \xi_{it} \quad (2)$$

where T_{it} denotes teacher inputs and can be a single factor for a teacher effect, S_{it} , P_{it} , Z_{it} denote school, peer, and other classroom inputs, respectively, ϕ_i is the fixed contribution of student and family, and the error term is $\xi_{it} = \varepsilon_{it} - \lambda \varepsilon_{it-1}$. The parameters of the model are estimated using least squares with models that include indicators for students and teachers (i.e., student and teacher fixed effects) along with the other variables.

Numerous applications use variants of model (2) to study teachers. Some applications assume $\lambda = 1$ and model the first differences in achievement or gain scores; however, others have used $\lambda = 0$ which results in fixed effects analysis on current-level scores

rather than gain scores. In other applications, λ is estimated by including the lagged prior scores as a predictor in a linear regression model. Some variants of model (2) treat ϕ_i as zero and some attempt to estimate both λ and the student coefficients while accounting for the complexities this creates for estimation.

If the students' potential outcomes for a teacher and the associated context are described by a model analogous to (2), then model (2) is a structural model and estimated effects of teachers are defined by the contrasts of the coefficients in γ_T . Teacher-level estimates can be obtained using linear regression techniques under the assumption that students assigned to any teacher's class differ from students assigned to other teachers' classes in terms of their general levels of family inputs (ϕ_i) and their prior achievement scores (A_{it-1}), but not in terms of unobserved factors related directly to their current level of achievement or to their achievement with their assigned teacher. That is, for students assigned to any given teacher, the distribution of the ξ_{it} must not differ from the distribution for other students and must have mean zero.

Statistical models

Statistical modeling approaches to value-added modeling evolved from the hierarchical linear model (HLM) framework which specifies the sources of variance at each level of a hierarchical data structure linking repeated scores to students and students to classrooms, teachers, and schools. One example of this class of models is the "layered model" originally used by the Tennessee Value-Added Assessment System (Sanders and Rivers, 1996; Sanders et al., 1997). HLMs are all variants of the following model, sometimes referred to as the variable persistence model, presented here for 3 years of scores on a single test:

$$\begin{aligned} A_{i1} &= \eta_1 + \gamma_{s1}S_{i1} + \gamma_{T1}T_{i1} + \gamma_{X1}X_{i1} + \zeta_{i1} \\ A_{i2} &= \eta_2 + \gamma_{s2}S_{i2} + \gamma_{T2}T_{i2} + \gamma_{X2}X_{i2} + \omega_{21}\gamma_{s1}S_{i1} + \alpha_{21}\gamma_{T1}T_{i1} + \zeta_{i2} \\ A_{i3} &= \eta_3 + \gamma_{s3}S_{i3} + \gamma_{T3}T_{i3} + \gamma_{X3}X_{i3} + \omega_{32}\gamma_{s2}S_{i2} + \alpha_{32}\gamma_{T2}T_{i2} + \omega_{31}\gamma_{s1}S_{i1} + \alpha_{31}\gamma_{T1}T_{i1} + \zeta_{i3} \end{aligned} \quad (3)$$

where η_t denotes overall means for the population each year, S_{it} is a vector of indicators identifying each school's share of the instruction for student i in school year t and T_{it} is an analogous vector for teachers. The elements of γ_{st} and γ_{Tt} are normally distributed random variables representing school and teacher effects that are assumed to be independent across schools, teachers, and years. X_{it} denotes vectors of student variables. Finally, $\zeta_i = (\zeta_{i1}, \zeta_{i2}, \zeta_{i3})'$ are multivariate normal variables with mean zero and an unspecified covariance matrix Σ , and are independent of teacher, school, and other student effects. The α and ω parameters measure the fadeout of teacher and school effects and can be estimated from the data. Model (3) may be extended to include more years of testing or multiple subject tests. A demonstration of how to fit model (3) can found in Doran and Lockwood (2006).

Restrictions to this model recover most of the other commonly used statistical VAMs. For example, the layered model is a special case of model (3) with no school effects (i.e., all the elements of all the γ_{st} are set to zero), no explicit controls for students' characteristics (i.e., all the elements of all the γ_{Xt} are set to zero) and all the α are set to one so that there is no fadeout of teacher effects. Another special case of model (3), referred to as cross-classified hierarchical linear models, also sets all the α (and ω) to one but specifies $\zeta_{it} = a_i + b_it$ with (a_i, b_i) assumed to be jointly normally distributed variables, to account for the situation where students are grouped differently in classes over time. Traditional HLMs assume students progress with the same classmates and are special cases with α (and ω) set to zero and correlation among ζ_{it} treated as zero.

The model parameters, including the α (and ω) parameters, can be obtained via maximum likelihood or Bayesian methods (Boedeker, 2017; Mai and Zhang, 2018). Bayesian methods have computational advantages and provide a principled method for making many desired inferences about teachers that account for uncertainty in all the model parameters.

Two-step VAMs

To reduce the increasing computational burden of calculating the estimates in model (2) and model (3), a two-step approach was developed. This approach is commonly referred to as an average residual model. The VAM presented in the Measures of Effective Teaching (MET) Research Report (Kane et al., 2013) and another presented in the work of Chetty et al. (2014b), among others, are examples of a two-step model. For instance, the MET fixed effects model, similar to model (2), estimates the expected achievement for each student based on their own and their peers' baseline scores and demographic characteristics:

$$A_{it} = X_{it}\beta + \bar{X}_{jkt}\gamma + \theta A_{it-1} + \lambda \bar{A}_{jkt-1} + \varepsilon_{it} \quad (4)$$

where the subscripts i, j, k, t represent the student, teacher, section/school, and year, respectively. The model statistically controls for the student's baseline score (lag score), A_{it-1} , the student's demographic characteristics, X_{it} , classroom-averaged baseline achievement score, $\bar{A}_{jkt-1}$, and classroom-averaged demographics, $\bar{X}_{jkt}$. The teacher-level value-added estimates are then calculated in step two. The second step estimates a teacher effect for achievement measure A_v as the average of the differences between each student's expected achievement based on model (4) and their observed achievement for year t . Technically, the value-added estimate for achievement measure A , teacher j , section k , and year t , is the average of the student model (4) residuals or the unexplained heterogeneity. Model (4) is limited to estimating a separate teacher value-added estimate for each univariate measure of student achievement.

Alternative modeling approaches

In other applications, analysts develop approaches for estimating value-added teacher effects that have face-validity to teachers and other stakeholders. For example, applications sometimes estimate teacher effects with simple averages of their students' gain scores or their residuals from a linear regression model predicting current achievement scores with a single prior score. Although these modeling approaches might be special cases of the models listed above, they are applied in practice with the simple notion of measuring growth as a means of estimating value added in a way that is more easily understood by stakeholders.

One prevalent example of a growth modeling approach that was developed to be more accessible to teachers and stakeholders is the student growth percentile (SGP) model (Betebenner, 2009), which can be readily estimated in the SGP package (Betebenner et al., 2020) for R. Similar to models (3) and (4), the SGP model estimates teacher effects by relating each student's current year score to their prior year score, but these estimated effects are instead presented as changes in percentiles, which are more easily understood by stakeholders. Technically, to calculate a student's growth percentile, a SGP model uses quantile regression to estimate the conditional density of a student's current achievement score conditioned on their prior achievement scores. Individual SGPs are then aggregated at a teacher or school level to provide evaluation estimates (e.g., the mean or median of the individual student SGPs in a class are used for a teacher estimate).

Each SGP represents the probability of observing a student's current achievement score conditioned solely on their prior achievement. Prior achievement can be determined by any subject and from any measure of student achievement, but in practice, this is often limited to one or two prior achievement scores, resulting in SGPs that are well approximated by percentile ranks of residuals from a linear regression model of current on prior scores (Castellano and Ho, 2013). The model can also be conditioned on other covariates such as student background, but SGPs in practice have excluded other covariates and relied solely on prior achievement measures.

Although these alternative modeling approaches might be appropriate for developing an accountability system that is acceptable to educators, the statistical properties of the resulting estimators still suffer from the same limitations as and potentially more than those resulting from models (3) and (4) (e.g., Castellano and McCaffrey, 2017). Therefore, methods that evaluate the properties of value-added modeling procedures are needed, as are tactics that emphasize the value of both face-validity and good statistical properties to educators and policymakers.

Limitations and concerns with application

As with any model, applications of VAMs are subject to limitations due to the assumptions of the model. Much of the concern around value-added modeling has been related to its widespread application in education to measure individual teacher effects, especially after the passing of federal and state regulations that require teacher evaluation systems primarily rely on measures of student achievement. Though research has shown teachers vary dramatically in effectiveness as measured by VAMs, the use of VAMs in high-stakes decisions about individual teachers has resulted in controversy and led to the critical evaluation of common VAM estimates. In response to the increasing debate on the use of VAMs in education, the American Statistical Association (ASA) issued a statement (2014) on the use of VAMs in educational assessment. This statement raised numerous cautions about the use of VAMs, including concerns of bias, precision, and stability of value-added modeling estimates. The following sections discuss each of these limitations and concerns.

Bias

VAMs are expected to produce unbiased estimates of a teacher's contribution to student learning. The three sources of bias that have consistently been raised as most problematic are (1) nonrandom assignment of students to schools and teachers within schools; (2) improper assumptions about persistence/fadeout of different factors influencing student achievement; and (3) improper assumptions about test score scales.

Non-random assignment

The fundamental problem of inferring teacher effects from observational data is that students are not randomly assigned to schools or teachers. The students taught by different teachers have systematically different characteristics, and unless properly controlled through statistical adjustment, these differences can introduce bias into estimated teacher effects. Bias of teacher-level effect estimates is an issue when students are disproportionately assigned to schools or classrooms based on background characteristics related to student outcomes and true teacher effects. The non-random assignment of students to schools and teachers based on such characteristics introduces systematic differences in student achievement across schools and classrooms that may be confounded with teacher effects (Ballou et al., 2004). This type of confounding makes it difficult to disentangle systematic differences in achievement due to non-random assignment from a teacher's true effect on student learning and may result in biased value-added estimates that over- or underestimate a teacher's true effect.

To combat the systematic differences in student achievement, student-level background characteristics can be introduced as covariates in the model. However, when student background characteristics are correlated with teacher effects, including student-level covariates can mask the effects of teachers and overcorrects for background characteristics, resulting in the underestimation of true,

latent teacher-level effects. For example, if highly effective teachers are assigned to affluent students, socioeconomic status becomes a proxy for teacher quality and true teacher effects are underestimated. [Lockwood and McCaffrey \(2007\)](#) suggest that under the right conditions and sufficiently many prior tests, covariates are unnecessary to control for heterogeneity among classrooms, but in practice this decision to include certain demographic covariates is often not statistically driven, but rather dictated by state, federal and local regulations. There may also be practical limitations on the number of prior test scores available to include in the model. Ultimately, there is a trade-off between potentially confounding teacher effects with student-level variables and potentially biasing teacher effects when deciding on the inclusion of demographic covariates in the model.

Several recent studies, including quasi-experimental and experimental studies, have examined the extent of bias in VAM estimates resulting from non-random assignment ([Kane and Staiger, 2008](#); [Chetty et al., 2014a](#)). The studies do not provide evidence to suggest that the VAM estimates are biased. As in all hypothesis tests, this does not prove the absence of bias, rather that studies have only indicated that the estimates are not significantly biased.

Persistence of inputs to achievement

It is generally accepted that achievement is a cumulative process and that achievement measured by standardized tests reflects both past and current inputs of educational and other factors as shown in model (1). As noted, models make numerous assumptions about the persistence of past inputs to allow for estimation of the effect of current teachers. For instance, many applications either implicitly or explicitly assume that teacher effects persist undiminished to all future years of student achievement.

However, there is evidence that teacher effects fade on standardized assessments and this can result in biased estimates. Studies that estimate α s in model (3) find past teacher inputs into future test scores decay rapidly ([McCaffrey et al., 2004](#); [Lockwood et al., 2007](#)). Studies using alternative methods also find that effects fade rapidly and never find persistence close to 100%. Limited empirical results demonstrate that errors in the assumptions about persistence can lead to biased estimation of the variability of teachers and systematic errors in teacher effect estimates.

Scaling and limitations of achievement measures

The construction and scaling of instruments used to measure student achievement also present issues when estimating teacher effects. Typically, measures of student achievement are assumed to be on a comparable interval scale, where any difference in scores has the same meaning across the entire scale and scores are directly comparable across years ([Schafer, 2006](#)). For example, a student with test scores of 60 and 70 in consecutive years increases their score by 10 and is assumed to have made the same amount of growth as a student with scores of 30 and 40. However, linking scores from different tests to a single comparable scale may require nonlinear transformations, where rates of growth differ in meaning across all ability levels. That is, students with different levels of ability may have the same rates of achievement on the original test scales, as demonstrated in the previous example, but after transforming the scores nonlinearly to a single developmental scale, the students could potentially have different rates of change given an increase of 10 which may subsequently impact teacher effect estimates ([Martineau, 2006](#)).

Teacher effect estimates may also be sensitive to the alignment of achievement test content with curricula, and the weighting of test content to obtain one overall achievement score. VAMs can only be used to estimate the student aptitude that is measured by the achievement test. Varying curricula and test content across grades amplify the complexity of measuring growth in a multidimensional domain. The potential impact of such test construction and scaling issues on teacher effect estimates should be considered. Most VAMs rely on only modeling quantitative measures of student achievement, such as standardized test scores, but the RealVAMs ([Broatch and Lohr, 2012](#)) model is a multivariate VAM that allows the estimation of teacher effects on other types of measures of achievement too (see [Broatch et al., 2018](#) for details on using the R package “RealVAMS” to estimate this model). Although sensitive to the same scaling issues and limitations of typical achievement measures, the RealVAMs model allows the simultaneous modeling of achievement test scores with discrete measures of student success, such as whether a student graduated from high school, to compare teacher effect estimates across multiple potential measures of success.

Different modeling approaches place more or less stringent requirements on the scaling of measures of student achievement. Model (3) makes less stringent assumptions about scaling than models that assume complete persistence, and this model or variants of it might be better suited for some test score data. However, limitations in the scale and test score transformations might invalidate model (3)’s assumptions of normality and implicit linearity in the relationships between scores from pairs of years. Another approach to combat the issue with test scaling is to use SGPs. By comparing student “growth” rather than achievement scores, SGPs do not rely on scaling for estimation, yet aggregated SGPs are known to suffer from the same bias issues as aggregated residuals. Teachers with lower achieving students have underestimated effects and vice versa for teachers with higher achieving students ([Castellano and McCaffrey, 2017](#); [McCaffrey et al., 2015](#)).

Concerns about precision and stability of estimates

Bias in estimated effects is of particular concern because the goal of VAMs is to evaluate teacher performance on student achievement without conflating teachers’ effects with their students’ backgrounds. However, bias is not the only threat to the utility of value-added modeling estimates. Value-added modeling estimates typically lack sufficient precision to support desired inference, especially those related to high-stakes decisions. The lack of precision and the instability, or variability, of teacher effect estimates across years leads educational practitioners to question whether the value-added modeling estimates are capturing teacher effects, or noise. Studies that report precision of individual effects generally show that annual teacher-level estimates have very large errors. For

example, standard errors are typically sufficiently large that about two-thirds of estimated teacher effects are not significantly different from average. Confidence intervals of teacher-level effects are wide and relative rankings contain substantial errors, so that only about 30–35% of teachers ranked in either the top or bottom quintile in 1 year remain there in the next year (Schochet and Chiang, 2013). Similarly, studies consistently find that the correlation of estimated effects from pairs of adjacent years is low, ranging from less than 0.2 to typically no higher than 0.5 (McCaffrey et al., 2009).

This lack of precision in estimates may be a direct result of model specification and the measurement error inherent in measures of student achievement. It has been reported that two different tests on the same subject can result in vastly different value-added modeling estimates of teacher effects (Lockwood et al., 2007; Papay, 2011). When a VAM includes student- or teacher-level covariates, the estimates of teacher effects tend to increase in variability, thus decreasing the precision of the estimates. Although their shown benefits are limited, shrinkage estimators where the teacher value-added estimates are shrunk toward a Bayesian prior (typically an average teacher value-added) have been used to reduce the standard error of these estimates. These shrinkage estimates have been used in the District of Columbia, New York City, and Los Angeles (Herrmann et al., 2016).

Due to the lack of precision, value-added modeling estimates have been compared with other measures of effectiveness. Evidence from large scale projects including the MET Project (Kane et al., 2013), report moderate positive correlations between value-added measures of teacher effectiveness and other measures of teacher effectiveness, such as principal evaluations, parent evaluations, and classroom observations. These positive correlations with other metrics have supported the use of value-added modeling teacher estimates, but researchers advocate for these estimates to comprise only a portion of a more comprehensive teacher evaluation system.

Summary

Within education, VAMs are a popular tool for measuring the effects of individual teachers on student achievement. Although there is no consensus about the best VAM, there is a general consensus that estimating effects with complex models like models (2), (3), and (4) with multiple years of test scores provides more accurate estimates of teacher effects than simple approaches or ad-hoc models. Concerns of bias, precision, and stability of value-added modeling estimates have been researched extensively in recent years and researchers encourage careful use of VAMs to appropriately make inferences about the effects of educational inputs. Regardless of the shortcomings of the current models, value-added assessments are clearly an improvement over other metrics used in accountability and provide a valuable attempt to use sophisticated methods to draw the most from increasingly available longitudinal test score data.

Automated scoring usually refers to a collection of batch-process or real-time machine-grading approaches that can differ dramatically depending upon the nature of the constructed-response (CR) task being posed and the expected answer. Two classes of CR task might be distinguished (Bennett, 2011). One class involves items that can be scored by exact matching, where the correct answer(s) are known in advance and a response only needs to be compared to the correct answer(s). A second class consists of questions that call for more complex answers that cannot be graded using exact-matching techniques. The automated scoring of these “complex CR” items is often accomplished through a “scoring model,” where features extracted from the responses are aggregated mathematically to produce a score. The resulting automated scores may be binary (e.g., right/wrong) or polytomous, depending on the grading rubric. This entry focuses on automated scoring of this complex CR class and on approaches that are used operationally in assessment programs and learning products.

Automated scoring has been deployed operationally in consequential assessments since the 1990s, when it was introduced for essay grading, medical problem solving, and architectural design (Clyman et al., 1995; Williamson et al., 1999).¹ Since that time, systems have been developed to grade low-entropy speech (e.g., reading a presented sentence aloud), high-entropy speech (e.g., describing one’s favorite sport), short text responses, mathematical expressions, graphical responses, and problem-solving processes in math and science, among other things.

Williamson et al. (1999) outlined the benefits that can be gained from automated scoring (see Table 1). Their list still applies.

We next discuss validation considerations that are common across content domains, uses, and systems. Then, we provide brief overviews of automated scoring in different domains. We close by offering some comments on several important trends in the field.

Table 1 Potential benefits of automated scoring.

<i>Benefit</i>	<i>Explanation</i>
Reproducibility	A response receives the same score if processed again.
Consistency	The same scoring criteria are applied to all responses.
Tractability	Depending on the method, the reasoning behind the automated scores can be traced, controlled, and explained.
Item specification	Automated scoring can encourage test developers to specify, construct, and modify CR items more finely.
Granularity	Responses can be evaluated at finer levels of detail.
Objectivity	Subjectivity is reduced through strict implementation of criteria.
Reliability	Objectivity, consistency, and reproducibility enhance test reliability.
Efficiency	The time and cost of grading open-ended CR responses is reduced.

Adapted from Williamson et al. (1999).

¹Research on automated scoring dates to Page’s (1966) seminal work on essay grading.

Validation of automated scoring

Kane (2013) argued that validation is iterative and adaptive, involving a network of claims and inferences, each of which depends on assumptions, with some assumptions relying on the plausibility of other assumptions (Kane, 2006, 2013). These claims, inferences, and assumptions are woven together in an interpretive argument that underlies score meaning and use. A single study is insufficient to validate the interpretive argument; instead, a more programmatic approach is typically required.

For the case of automated scoring, on what should that research focus? An important efficiency motivation for many testing programs is to determine whether human rating can be reduced or replaced without any practically important validity loss. In this context, the level of validity provided by human rating is generally taken at face value based on rater selection criteria, training, daily qualification, and operational monitoring. As a result, most validation research has focused on agreement between automated and human scores. However, many authors have argued that concordance with human ratings is not nearly enough (Attali, 2007; Bennett and Zhang, 2016; Williamson et al., 2012). Bejar (2012) argues convincingly that any attempt to validate automated scores through agreement with human ones must first marshal evidence to support the validity of that criterion. But more fundamentally, justifying the uses and interpretations of automated scores calls for a broad collection of evidence consistent with the general argumentative approach (Bennett and Zhang, 2016; Drasgow et al., 2006).

What should constitute this collection of evidence has been discussed extensively in the literature. Even though most of the proposed frameworks are for the scoring of text and spoken responses, the key elements are applicable across domains. For example, Williamson et al. (2012) emphasized five areas: construct representation and relevance, relationship to human scores, association with external measures, generalization across tasks and test forms, and consequences. Xi (2010) suggested five similar areas but with special emphasis to impact on students' test preparation behavior and on teaching and learning practice. Bejar et al. (2016) begin with design, distinguishing evidence extraction (i.e., detection and judgment of construct-relevant features) and evidence synthesis (i.e., quantitative aggregation of judged features). Following Bejar et al., Evanini et al. (2017) proposed designing spoken-language assessment with automated scoring in mind, validity being the most important scoring-design and implementation factor.

Whereas assembling a broad collection of evidence is important, that evidence should not be assumed to speak to validation of the automated scoring system itself; that is, results do not characterize the *system's* validity. In fact, validation is highly conditional (Bennett and Zhang, 2016; AERA, APA, NCME, 2014), characterizing *scores* that are dependent on the purpose of the assessment, its stakes, task types, and the examinee and user populations (Zhang et al., 2019).

The conditional nature of validation is recognized in the various frameworks through their concerns for population-group fairness, both with respect to the meaning of scores and their use. That is, automated scoring should *function* in the same way across groups, especially socially protected ones. *Functioning* can be taken broadly to mean all the areas noted by Williamson et al. (2012): construct representation and relevance, relationship to human scores, association with external measures, generalization across tasks and test forms, and consequences.

Fairness issues have recently received more general attention in the artificial-intelligence (AI) community due to highly publicized differential functioning in a wide array of AI applications (e.g., facial recognition, recidivism risk) (Angwin et al., 2016; Grother et al., 2019). Those issues arose in part from failing to appropriately represent population groups in the development of AI models and neglecting to evaluate system functioning with sufficient samples from those groups. In automated scoring—a subfield of AI—very few such studies have been published. Results to date suggest the presence of potentially important disparities in how some systems function across at least some demographic groups (Bridgeman et al., 2012; Ramineni and Williamson, 2018), implying a need to investigate differential functioning much more comprehensively.

Perhaps also under-emphasized in discussions of the validity of automated scoring is the generalizability component, specifically that related to reliability. Haberman et al. (2015) distinguish two reliability types: assessment accuracy and scoring accuracy. *Assessment accuracy* is the reliability of the total test score to which the CR scores contribute in whole or in part. When graded by humans, the *scoring accuracy* for a CR task will be imperfect because of subjective judgment. Automated scoring has the advantage of perfect accuracy, primarily because the same response will receive an equivalent score if the model remains unchanged (Yao et al., 2019; Zhang, 2013), or the system is not swapped out for another.

Researchers have investigated reliability where the prediction target was the human true score (i.e., the expected score taken over an infinite number of independent human judges). Yao et al. (2019) employed the summed human true score taken across essay responses as a target. They reported improved scoring and assessment accuracy when using automated feature scores (e.g., grammar, usage) plus one human rating, over using only one human rating. Using double human scores led to even higher scoring accuracy in two of three testing programs investigated and generated the highest assessment accuracy. In the context of automated scoring of spoken responses, Zhang et al. (2019) showed that using human scores alone can produce fairly high scoring accuracy and assessment accuracy, with only marginal improvement from adding machine-generated feature scores.

For additional discussion of automated scoring validation, see Bejar (2011), (2017), Bennett (2006), Bennett and Bejar (1998), Bennett and Zhang (2016), Williamson et al. (2006), Clauser et al. (2002), Xi et al. (2012), Yang et al. (2002), Yan and Bridgeman (2020), Zhang et al. (2019).

Operational uses of automated scoring

Automated scoring of essays

The most common operational uses of automated scoring in educational assessment are for grading essay responses. The essays are typically written in response to a short prompt, though in some cases the prompt may reference source material (e.g., several short documents) to be consulted as part of the composition task. Prompts may direct examinees toward different writing purposes, including informational, persuasive, and narrative.

Essay scoring systems are often used alone or in conjunction with human raters to provide scores and/or qualitative feedback (Stevenson and Phakiti, 2013). The evaluated characteristics may include linguistic ones (e.g., grammar, mechanics, text coherence, sentence structure and variety, vocabulary sophistication and choice, aspects of content) and/or *n*-grams (i.e., contiguous sequences of *n* items composed of letters, syllables, or words). Features that quantify those characteristics are aggregated to generate a score intended to predict the one a human rater would assign. The prediction models may range from multiple linear regression and cumulative logit, which are simpler to explain, to more inscrutable machine-learning models, such as support-vector machines and K-nearest neighbor, trained on human-rated responses. Combinations of models may also be used with decision rules to accumulate over their results.

The most well-known of the operationally deployed English-language systems are PEG (MI, 2021), IntelliMetric (IntelliMetric, 2021), Intelligent Essay Assessor (Pearson, 2021a), Turnitin Scoring Engine (Turnitin, 2021), and e-rater (ETS, 2021). Some of these systems have also been employed to score text in other languages (e.g., Intellimetric). In addition, scoring systems are found as components of instructional writing products, including Criterion (ETS Global, 2021), WriteToLearn (Pearson, 2021b), Turnitin Scoring Engine (Bolkan, 2015), and WritingPal (Adaptive Literacy Technology, n.d.). These products generally offer instant structured feedback, as well as scores, intended to help users improve English composition skills.

With respect to validation, of critical importance is that, regardless of some vendors' claims, automated essay scoring systems do not understand what they process in the way that a human does (Bennett and Zhang, 2016). Consequently, they are in principle considerably less capable with respect to content-related factors than are human graders. This fact makes the systems susceptible to construct underrepresentation in that they do not appear to accurately judge such characteristics as factual correctness, unusual organizational structures, quality of argument, appropriateness of evidence supporting a position, or quality of rebuttal (Zhang et al., 2016). They may also be subject to construct-irrelevant variance emanating from such gaming strategies as irrelevant text or employing rare vocabulary (Bejar et al., 2014; Zhang et al., 2016). For these reasons, automated scoring may often be combined with human rating in consequential testing programs (e.g., TOEFL iBT, GRE Analytical Writing, GMAT Analytical Writing Assessment), but used as the sole scoring method in lower-stakes applications (e.g., Smarter Balanced interim assessments).

Given the conditional nature of validation, it is impossible in the context of this entry to summarize the relevant literature for the various uses to which the most-commonly employed systems have been put. Bennett and Zhang (2016, Tables 7.5 and 7.7) give an illustration for e-rater and GRE Analytical Writing, in which evidence is assembled relevant to the meaning of human scores as a criterion, as well as the meaning of automated scores in relation to that and other criteria. Their example shows how claims might (or might not) be supportable given the available evidence. See Shermis and Burstein (2013) for more information about particular systems and research relevant to them.

Automated scoring of spoken responses

Speaking tasks are often divided into low complexity (or "entropy") and high complexity (high entropy). Responses to low-entropy tasks are predictable, as when one is asked to read aloud from written text or restate an orally presented sentence. High entropy tasks, in contrast, produce more spontaneous speech.

Among the notable differences between the automated scoring of essays and speech is the need in the latter to recognize what was said, thereby adding a processing layer. That layer initially introduced significant error because a portion of what was said would inevitably be misinterpreted, more so for spontaneous than for low-entropy speech. Over the last decade, the accuracy of speech recognition has improved considerably so that the error has diminished considerably. However, for nonnative speakers of English, recognition may still represent a source of nonnegligible error (Chen et al., 2018). A second important difference is that during recognition, construct-relevant process features can be extracted (e.g., prosody, fluency, pronunciation) for inclusion in scoring. The subsequent steps are not unlike text scoring, involving the use of techniques from natural language processing to compute linguistic features. Then, the full set of extracted features is aggregated to create automated scores intended to predict what a human rater would assign (see Zhang et al., 2019, for a list of sample features). Of note in feature aggregation is that the same variety of modeling techniques as found in essay scoring may be applied, ranging from more explainable hierarchical regression models to impenetrable machine-learning ones, as well as combinations involving multiple models.

The most well-known operationally used English speech-scoring systems are probably Versant (Pearson, 2021a) and Speechrater (Chen et al., 2018; Zechner and Evanini, 2020; Zechner and Loukina, 2020). Those systems, or ones similar to them, are found in both operational assessments and learning products. Among the testing programs using such systems are PTE Academic, Duolingo English Test, TOEFL iBT, and TOEFL Essentials. Commercial products include TOEFL Practice Online (TPO), EduSpeak, Carnegie Speech, Duolingo, and Liulishuo. Some of these products, like Duolingo, evaluate speech in multiple languages, though typically in low-rather than high-entropy form.

With respect to validity, like essay scoring, issues of construct underrepresentation and irrelevant variance are pertinent. For example, automated speech scoring may inaccurately process responses with unusual characteristics. Yoon and Zechner (2017) listed several categories of such response, including no response/total silence, noise constant in the background, distorted recording, partially missing samples in the response audio, not the target expected language, and off-topic. Proper treatment of such responses is essential to fairness, as well as to establishing and maintaining the credibility of automated scoring.

For validation research related to the use of Speechrater for scoring TPO, see Chen et al. (2018) and Wang et al. (2018) for an example of human-machine agreement in (what appears to be) TOEFL iBT. A more dated discussion of Versant research can be found in Bernstein et al. (2010).

Automated scoring of short text responses

Short text responses run from a phrase to a few sentences intended to give facts, analysis, explanation, or conceptual understanding. Traditional approaches to automated scoring presume that the associated tasks have a small set of semantically correct answers which can be expressed as one or more concepts (Sukkarieh and Blackmore, 2009). Each of these concepts can then be represented in a canonical form as an answer key. The automated scoring system then attempts to recognize when a student's response paraphrases, or is implied by, that key. More contemporary methods, however, utilize ML approaches based on n-grams which, given enough training data, can distinguish among score categories and assign new responses to them.

Automated scoring of short text responses may be done in a variety of domains, including English language arts (reading comprehension, writing), history, science, and mathematics (to explain an answer). Among the operationally used systems are the Turnitin Scoring Engine (Bolkan, 2015), Intellimetric (Intellimetric, 2021), and the Intelligent Essay Assessor (Pearson, 2021a). The Smarter Balanced interim assessments use such scoring operationally (Cambium Assessment, undated).

Automated scoring of STEM responses

Automated scoring has been used operationally with a range of response types in disciplines related to science, technology, engineering, and mathematics (STEM). In science-related disciplines, the longest-standing use for consequential assessment has been in medical problem solving, both for licensure as well as for instruction.

The United States Medical Licensing Examination (USMLE) includes a section of computer-based case simulations (USMLE, 2018). A unique aspect of the measure is that the presented problem changes as the examinee interacts with it (e.g., the patient's condition may change, test results may arrive). USMLE automated scoring consequently must consider not only such outcomes as the final diagnosis and prescribed treatment but also the *process* used to manage the patient. Examinee responses related to that process (e.g., tests ordered or not ordered, initial treatments prescribed or not prescribed) are combined with outcome information by using rules derived from domain experts as to what constitutes a professionally responsible performance. Rather than choosing features and aggregation rules empirically, in this approach, humans define those parameters, as well as perform quality control when the scores are produced (Clauser et al., 2016). Margolis and Clauser (2020) describe the USMLE simulations in detail, as well as evidence related to some validity aspects. Ward et al. (2019) review validity evidence related to the use of computer-based case simulations in health-care licensure and education more generally.

A similar approach was used up until recently in the design section of the Architect Registration Examination (ARE; Bejar, 1991; Braun et al., 2006), also a licensure assessment employing methodology relevant to educational measurement. Unlike USMLE, the ARE design problems were not dynamic—that is, the examinee created a drawing in response to a given specification. Scoring was based on domain-expert propositions and aggregated to produce a pass-fail decision.

Among instructional applications, Inq-ITS is an intelligent tutor, or personalized learning system, intended to develop middle-school students' skills in science inquiry (Gobert et al., 2018). Tasks take the form of scaffolded investigations. As in the USMLE computer-based case simulations, both process and end products are evaluated but, in this case, to judge proficiency on specific inquiry practices and their respective sub-skills. Both propositional and ML techniques are employed, along with Bayesian Knowledge Tracing to amalgamate information (Corbett and Anderson, 1995). See Mislevy et al. (2020) for a detailed treatment of the method, as well as a more general discussion of automated scoring in learning systems.

Far simpler methods are generally used in the scoring of mathematical problems. Aside from short text responses, several additional tasks are amenable to automated scoring, including equations or expressions (where there is a single mathematically correct answer that can take many different surface forms) and the symbolic work leading to the final answer. With respect to the former, in combination with its Equation Editor, Pearson's Math Reasoning Engine is operationally employed to score tasks in consequential assessments (Pearson, 2021a). (See Bennett et al., 1997, for an early example of the scoring technique.) Scoring of symbolic work leading to a final answer is more challenging unless enough constraint is added to limit the paths that can be taken (e.g., breaking the problem into smaller steps, as in the case of such learning systems as Carnegie Learning's MATHia).

Automated scoring of response processes

In the above sections, process data figured into operational scoring in medical problem solving, science inquiry, and speech, among other areas. In addition, process data have been collected in operational international and national assessments, where they have been used to enhance interpretation and inform decisions about how to treat specific cases. For example, the 2019 TIMSS Problem

Solving and Inquiry Tasks were administered in over two dozen countries (Mullis et al., 2021). Event timing, navigation from screen to screen, scrolling, and the use of calculators and rulers were evaluated to examine student progress through the tasks so that non-response data could be more carefully analyzed, distinguishing between students who stopped responding early and those who ran out of time. Process data also permitted examination of how interactive task features were employed and whether that use might have contributed to performance that was lower than expected. (Similar data were collected in the 2017 NAEP eighth grade mathematics assessment and are available for analysis in restricted use data sets, NCES, 2020.)

Of note is that, although process data have been collected in these assessment programs for some time, there is as yet no indication that the underlying analyses are anything more than custom point-in-time applications. That such data are being reported, however, suggests that formalized automated systems will eventually result.

Emerging trends

As has been suggested throughout this entry, the rise of ML approaches is perhaps the most important development in the past decade. Tippins et al. (2021) raise concerns with respect to the use of these approaches in personnel-selection contexts, some of which pertain to high-stakes educational assessment. Chief among those concerns are the lack of a theoretical basis for predictors (e.g., *n*-grams in writing or speaking assessment); transparency (due to the black-box nature of the methods and their oftentimes-designation as trade secret); and limited validity evidence (compounded by the lack of a theoretical basis and limited transparency).

Concerns for fairness are also an issue. Although fairness may be investigated empirically, as with validity, the absence of a theoretical basis and lack of transparency make meaningful evaluation challenging. To be sure, these concerns are arguably more serious with respect to high-stakes uses of ML than with formative assessment in learning products. However, the potential for inequity in learning should not be ignored.

A second emerging trend is legal. Because machine algorithms are being used to make consequential decisions in contexts ranging from lending to employment, governments have begun to issue regulations. The European Union's General Data Protection Regulation (GDPR), for example, granted the right to an explanation of an algorithmic decision that "significantly affects" an individual (Meyer, 2018). Similarly, the OECD Recommendation of the Council on Artificial Intelligence (OECD, 2019) states that "AI Actors should commit to transparency and responsible disclosure regarding AI systems ... to enable those adversely affected to challenge its outcome based on plain and easy-to-understand information on the factors and the logic that served as the basis for the prediction, recommendation or decision" (Section 1. IV.1.1). The G20 Ministerial Statement on Trade and Digital Economy (METI, 2019) contains the same language as the OCED Recommendation.

The growth of regulations and recommendations has encouraged the development of explainable artificial intelligence (XAI) (Adadi and Berrada, 2018; Gunning et al., 2019). This new field seeks to make AI decisions transparent to, and traceable by, humans. To the degree it is successful, when applied to automated scoring, XAI should increase validity by, for example, making construct relevance easier to evaluate. This evaluation, in turn, should make it easier to locate and eliminate predictors that function well empirically but have no substantive import.

Introduction

Imagine a world where every student is provided with a dedicated expert who could instantly review their work and provide them with feedback tailored to their interests and experiences. This expert could inspect the records of numerous other students to predict what educational intervention would be most helpful to their individually assigned student. These experts could inform teachers by providing an accurate real-time picture of their class, so they can focus their effort where it is most needed. Furthermore, each expert would move with their student across classes as their student progressed from one grade to the next, and provide personalized, up-to-date guidance to help their student navigate the educational system and eventually start a career.

Currently, private one-on-one tutoring provides some of the support necessary to fulfill this dream, but the cost of these tutors limits their use. For example, a high-quality tutor can teach based on the student knowledge, adapt to this student's misunderstandings, create opportunities to apply knowledge, provide motivation, adjust based on the student's emotions and provide tailored instructions on exactly which aspect of the learning experience a student can improve on next. The gold standard result of one-to-one tutoring is an increase by two standard deviations compared to students who learn via classroom-based instruction (Bloom, 1984), an opportunity that would be transformative to provide to all students but is simply not affordable to most parents and students.

With the advances in computation, modeling of learners, and Machine Learning (ML) methods, the field of Learning Analytics (LA) emerged to not only fulfill the role of an individual tutor to all students (regardless of socioeconomic status) by personalizing instruction to the student often within digital environments but also to report this information to the teacher. In sum, the goal of LA is to measure, collect, analyze, and to report data about learners and their contexts, for purposes of understanding the learner and identify ways for providing the above-mentioned type of personalized, adaptive instruction in digital learning environments (LAK 2011: 1st International Conference Learning Analytics and Knowledge, 2011).

A well-designed digital learning or interactive assessment environment provides opportunities for human experts (e.g., teachers, assessment developers) to adapt the environment to their needs and make valid inferences about the layers of knowledge, cognitive processing, and affect for each student with the help of LA. These inferences can inform how personalized feedback and one-on-one tutoring is provided to students at a low cost as well as alert teachers when students are struggling (for a review of computerized *Intelligent Tutoring Systems* see Koedinger et al., 1997; Mousavinasab et al., 2021; VanLehn, 2011). One of the main goals of LA research is to optimize each student's learning in and out of the classroom providing teachers with detailed information about the student and class. For example, with LA operating in a digital learning environment, an ML algorithm may identify the misconception at an early stage in students' learning and provide feedback directly to the students and/or to the teacher to quickly correct the misconception. This opportunity may not occur without a detailed level of personalization brought by LA and ML resulting in some students being disadvantaged. Thus, bringing LA and ML approaches together offers each student a closer chance of an equal opportunity in learning as well as assessment of learning.

In this chapter, we provide a general introduction to the primary concepts and areas of research within LA, and highlight the different analytic approaches used to understand and support both students and teachers. As research within LA increasingly applies and extends ML methods, we highlight research along the three branches of ML (i.e., supervised, unsupervised, and reinforcement learning) which has made significant advancement toward the vision of high quality, adaptive or individualized instruction. These advancements make it possible to adapt and recommend instruction, provide immediate feedback, and present score reports as students' progress through the learning experience. We conclude by pointing out the trends and opportunities for the future of LA.

Learning Analytics

Learning Analytics (LA) and Educational Data Mining (EDM) are two fields that aim to measure, collect, analyze, and to report data about learners. Despite some differences, the co-founders of both fields admit that researchers in the field often cross-publish between these two fields because of the common goal of aiding education through analytics and theory (Baker and Siemens, 2014). In this article, we use the term LA in a broader sense, and we include research from both EDM and LA to convey to the readers how analyzing educational data can provide actionable information to students, teachers, and other educational stakeholders. This is a timely message as remote and distance learning becomes increasingly common and solutions such as LA are needed.

LA describes a broad array of analytic approaches that provide scientific and data-driven insights to improve education. While the field of LA brings together diverse topics of research that touch many different types of educational environments, much of the work takes advantage of technology to collect data and drive change. Common educational environments studied within LA include learning management systems, Intelligent Tutoring Systems, and Massive Open Online Courses (MOOCs). These computerized educational environments produce complex data about the learning process such as log files resulting from student interaction. Through the analytic methods central to LA, this data feeds the knowledge discovery process and inspires the development of theories and methods to further improve learning. Fig. 1 illustrates the cycle of research in LA (based on similar figures by Khalil and Ebner, 2015; Romero and Ventura, 2020).

LA has dramatically increased our understanding of student learning by adapting student learning environments and providing teacher reports (for a review, see Baker and Siemens, 2014), via detecting affective states and modify learning experiences accordingly (e.g., D'Mello and Graesser, 2012; D'Mello et al., 2008), representing student cognition to improve math learning (e.g., Koe-dinger et al., 1997), creating and implementing optimal spaced practicing methods (e.g., Pavlik and Anderson, 2008; Walsh et al., 2018) and providing profiles of students characteristics in complex domains such as collaborative problem-solving (e.g., Andrews-Todd and Forsyth, 2020; Forsyth et al., 2020). Below, we briefly review the core concepts in LA research and applications of LA.

Student modeling

For many years, an important aspect of LA has been student modeling (Chrysafiadi and Virvou, 2013; Webb et al., 2001) which is a method of tailoring to the individual learner's needs based on detection (or assessment) of the immediate state of the learner. The focus of student modeling is to capture the affective, behavioral, and cognitive components which are important for student learning and complex assessments. Perhaps the simplest instantiation of a student model can be seen in educational assessments where the goal is identifying what a student needs to know to master a topic. For example, perhaps additional evidence is required to determine a student's mastery of a given topic in a computerized adaptive testing environment. Therefore, the environment adapts to present the student with additional questions to gather the needed evidence before moving on to a new topic (e.g., see Evidence-Centered Design; Mislevy et al., 2003). LA researchers have extended this concept of adaptation by considering a range of different learner models at various levels of granularity (see Zapata-Rivera and Arslan, 2021 for a brief review of different learner modeling approaches).

Fig. 1 The traditional research cycle within learning analytics.

Proficiency modeling

The focus of proficiency modeling is to identify what a student knows at a given point in time to either adapt content or provide instructional feedback to help the student reach their optimal performance (for review see [Pelánek, 2017](#)). One of the earliest proficiency modeling approaches, Bayesian Knowledge Tracing (BKT), was developed based on the psychological theory of skill acquisition ([Corbett and Anderson, 1994](#)) and has been adapted and used within numerous digital learning environments (for more details, see [Pelánek, 2017](#); [Ritter et al., 2015](#)). BKT considers not only what the student *knows* but whether or not the student is able to *do* the given skill (roughly corresponding to the concepts of *declarative* vs. *procedural* knowledge). The model requires that instructional designers identify knowledge components encompassing both types of knowledge that underlie each activity a student interacts with. For each Knowledge Component, BKT estimates a set number of states with specific semantics about the what the learner knows based on students item responses (e.g., “know”: a correct answer that accurately reflects student knowledge and/or skills; “guess”: an unlikely correct answer given the student’s previous answers; “slip”: an unintentional error). By observing the sequence of types of item responses generated by a learner, BKT estimates the probabilities that students are in one of those latent states. For example, a student may answer a problem correctly because they *know* the material or because they *guessed*. As the model is provided examples of a student performing a specific skill, it learns the probability that their actions reflect those latent states. These probabilities have valuable psychometric properties and use cases.

Since the development of BKT, there has been considerable work to refine, extend, and develop alternative approaches for estimating student proficiency. BKT has undergone many developments to include additional aspects such as general item difficulty (e.g., [Pardos and Heffernan, 2011](#)), adaptation (e.g., [Yudelson et al., 2013](#)), and skill dependencies ([Meng et al., 2019](#)). Logistic based models, such as Additive Factors Model (AFM; for review see [Durand et al., 2017](#)), can be implemented to derive the student’s current level of proficiency, difficulty of a skill, and learning rate of the skill (for more details, see [Cen et al., 2007, 2008](#); [Thai-Nghe et al., 2010](#)). AFM is a type of multi-dimensional item response theory that has been adapted to capture several assumptions about how people learn within an adaptive computerized learning environment focusing on tutoring, often referred to as Intelligent Tutoring System (ITS) (for review see [Graesser et al., 2012a](#)). Given the interpretability of the parameters and the numerous implementations available open source (e.g., [MacLellan et al., 2015](#); [Pardos and Dadu, 2018](#)), AFM has become a popular tool for both estimating student proficiency and identifying issues within tutoring systems (e.g., [Cen et al., 2006](#); [Goutte and Durand, 2020](#); [Long et al., 2018](#)). More recently, deep learning approaches which utilize ML algorithms (described in Section [Machine learning in learning analytics](#)) have started to be implemented to estimate student proficiency. Approaches such as Deep Knowledge Tracing has demonstrated how a ML method (i.e., a long short-term memory model) can be used to successfully predict student performance over sequences of items (for more details, see [Piech et al., 2015](#); [Wilson et al., 2016](#); [Xiong et al., 2016](#)). Finally, theories of how humans forget information have informed the creation of several proficiency models that consider both the impact of practice and time between practice opportunities when estimating student mastery of skills (e.g., [Eglington and Pavlik, 2020](#); [Pavlik and Anderson, 2008](#); [Walsh et al., 2018a,b](#)). These proficiency models have proved to be especially important in accurately capturing student knowledge across many, spaced sessions. Research comparing different proficiency modeling approaches, illustrates that there is no single approach that works best in all contexts but rather taking into account the domain and environment can reveal the optimal algorithm (e.g., see [Doroudi and Brunskill, 2019](#) for on the equitability of Knowledge Tracing methods). The most appropriate proficiency modeling approach varies depending on the type of data available, the structure of the learning task, the assumptions about skill dependencies and learning processes, and the desired use of these algorithm’s results.

Behavior modeling

Behavior modeling focuses on estimating features of the learner’s state beyond what they know, that may affect learner’s activity within an educational environment. Research on behavioral modeling targets a wide range of different states from affective states, motivational states, physical environment, learning relevant constructs (e.g., self-regulated learning) to states that capture more complex interactions between learners, their peers, and their instructors (e.g., collaborative learning). One type of behavioral modeling that is a flourishing area of research within the LA field focuses on emotion detection (for a complete review, see [D’Mello and Kory, 2015](#); [D’Mello and Graesser, 2012](#)). Specifically, previous research suggests there are six common cognitive-affective states experienced during learning: engaged concentration, confusion, boredom, frustration, delight, surprise ([Baker et al., 2010](#)). Interestingly, confusion is the cognitive-affective state most likely to lead to high levels of understanding ([D’Mello and Graesser, 2014](#)). [D’Mello \(2017\)](#) increased learning gains in an existing ITS by detecting and adapting to human emotion. He was able to detect emotions via multiple sources of evidence (i.e., facial expression, body movements, and linguistic cues). Although some pattern matching algorithms can automatically code some of these cues (e.g., FACETS which can match 14 facial movements to an input of a student face based on the research of [Ekman and Friesen, 1978](#)), these labels are still needed as input to an overall learning prediction model. This is certainly an exciting prospect, but the intuitively obvious issue was the difficulty of getting students in regular classrooms to wear sensors. Therefore, [Ocumpaugh et al. \(2012, 2015\)](#) discovered a method of detection without sensors for identifying student’s affective states in classrooms in an unobtrusive method referred to as the BROMP protocol, which identifies non-verbal body movements to detect engaged versus disengaged students. This method provides feedback to the teachers which allows them to intervene to maximize student learning and provides an additional source of evidence for validating and inspiring other detectors. Specifically, LA researchers introduced new detectors and methods for detecting cognitive-affective states in adaptive learning systems, such as ASSISTments ([Botelho et al., 2017](#); [Heffernan and Heffernan, 2014](#)) and Physics Playground ([Shute and Ventura, 2013](#)). Thus, behavior modeling continues to grow as an area where students’ current knowledge, affective states, and other factors can be included to personalize the learning experience.

Adaptation and recommendation

Proficiency and behavior modeling serve as a foundation for supporting adaptive instruction. However, how to change the system in response to information about the learner can vary depending on what actions are available within the system, the time scale of focus, and the learning goals the system is meant to support. The area of LA research focused on adaptation and recommendation targets the algorithms for implementing how the instructional system changes in response to the information provided by the student models described in the previous section. Adaptation and recommendation can exist at multiple levels of granularity within an educational system: within a practice item, across practice items, between lessons, or even between courses.

Within a given lesson researchers often make the distinction between *inner loop* and *outer loop* adaptation (VanLehn, 2006). Inner loop adaptation takes advantage of model-tracing, a means of tracking a student's problem-solving process and providing support based on students' actions. These methods often involve the use of rules or scripts to identify when the system should intervene (Brown and VanLehn, 1982). For example, Aleven et al. (2006) found that by developing 'bug' rules, a type of production rule (or *if-then* statement) that captured common misuse of hints within a tutoring system, could be used to intervene and provide feedback when these misuses occur. In a pilot study, Aleven et al. found that by providing this adaptation, they were able to correct maladaptive help seeking strategies. This approach of authoring bug rules has been extended to work in a wide range of learning environments from Intelligent Tutoring Systems (e.g., Tacoma et al., 2021) to MOOCs (e.g., Aleven et al., 2015). Inner loop adaptation can adapt to offer instructional support in less structured learning environments. For example, conversational agents have been used across a wide variety of domains in order to structure problem solving, probe student's knowledge and provide input similar to human tutors in the form of feedback which is discussed in detail in the next section (e.g., Graesser et al., 2001, 2014; Hobert and Meyer von Wolff, 2019; Rus et al., 2013). These agents offer input to students based on production rules that are structured to operate like real expert humans. Although agents have been used in numerous capacities across a variety of domains, conversational agents allow for natural language conversations between the student and artificial agent (e.g., Biswas et al., 2010; Gholson et al., 2009; McNamara et al., 2006; Olney et al., 2012; Ward et al., 2013). During natural language conversations, the human input is analyzed with natural language processing algorithms (e.g., Jurafsky and Martin, 2008; Landauer et al., 2013) to determine the intent of the human input and appropriately respond. This type of adaptive dialogue simulates the types of conversations human tutors might engage in when working with students and have been shown to produce similar learning gains to human tutoring (e.g., Graesser et al., 2004; Graesser et al., 2012a,b; Hu and Graesser, 2004; McNamara et al., 2006; Olney et al., 2012; VanLehn et al., 2007; VanLehn, 2011).

Adaptation that involves the selection of what activity students should perform next is referred to as *outer loop* adaptation. The area of research in outer loop adaptation referred to as a *Stopping Policies* which are set rules to determine whether a student should continue practicing a given skill or stop practicing a given skill and progress to new content (e.g., Pelánek and Řihák, 2018; Ritter et al., 2016; Sales and Pane, 2019). The stopping policy of mastery learning is based on student proficiency models such as BKT to estimate when a student knows or has "mastered" a skill. This type of adaptation is a means for an ITS to alter the pacing of material to match students' needs which lead to claims that ITS can produce double the learning gains in half the time of a standard brick-and-mortar class (Koedinger and Corbett, 2006). Distinct from *Stopping Policies*, research on *Instructional Policies* focuses on determining the order in which new content should be practiced (or order of instruction). This area of research encompasses a diverse array of analytic methods and can focus on a range of different levels of decision-making (e.g., Bassen et al., 2020; Iglesias et al., 2009; Khalid et al., 2020; Koedinger et al., 2013; Tarus et al., 2018). In subsection **Reinforcement learning**, we highlight in more detail efforts for ML to identify the optimal sequencing of instruction and practice; however, researchers have identified numerous promising approaches for generating recommendations often in the form of feedback that is sensitive to the data available and needs of the educational system.

Feedback and score reporting

Adapting to a specific human's needs by providing immediate feedback has a long documentation of being incredibly helpful to student learning (for a review, see Shute, 2008). Feedback is provided to students based on recommendations from LA which can be challenging as the feedback must be given at the perfect critical moment and be the correct type of feedback. LA helps identify critical moments where an intervention would be most helpful to a student (e.g., Pardo et al., 2019). However, there are various types of feedback that can be provided to help these students that have been outlined in a meta-review by Shute (2008). Although covering all types would be beyond the scope of this article, we would like to provide a couple of examples. One example is *verification* or simply telling a student whether an answer is correct or incorrect. This can help the student know when to either move on or try again but does not explain to the student how the answer is correct or incorrect. Another example is *elaboration* where the feedback explains multiple aspects about why the given answer is correct or incorrect. Immediate feedback during natural language conversations for tutoring may be more defined to mimic the types of feedback given by real human tutors in dialogic frameworks which are beyond the scope of this article to define (see chapter in this Encyclopedia by Graesser et al.). Moreover, it's important to note that there are still many more possible types of feedback which is why the research on the effect of different types of feedback on student learning is still continuously being explored (for a more recent review, see Mertens et al., 2021) and other types of information are given to stakeholders in the form of score reports.

Score reporting often refers to reports provided to stakeholders after a longer period of time (rather than immediate feedback) requiring information about the audience which could include students, teachers, parents and other stakeholders (Shute, 2008; Zapata-Rivera and Katz, 2014). The research on score reporting can be invaluable to understand what should be provided to each of the various stakeholders (e.g., Kannan et al., 2018a; Kannan et al., 2018b; Zapata-Rivera et al., 2018). Specifically, the needs, knowledge and attitudes of the intended stakeholder should be taken into account when providing a score report or creating a dashboard (Zapata-Rivera and Katz, 2014). However, providing a comprehensible summary information about student performance, strategies to solve a problem, knowledge and skills based on process data (i.e., log files that include user and system events together with their timestamps) can be challenging (Forsyth et al., 2017).

Teachers may have difficulty interpreting reported detailed information collected via LA such as scores relating to cognitive psychology constructs that are correlated with learning (e.g., number of words generated; Zapata-Rivera et al., 2018). Score reporting with information from process data must be understandable by all stakeholders (e.g., the student, teacher, and parent). For example, after realizing that teachers were not understanding the reported material, Forsyth et al. (2017) used an artificial agent to explain each construct to teachers whenever they needed a clarification. This example highlights the gap between what LA researchers may think is important based on literature and what teachers perceive as needed in the classroom. For more details on reporting this type of process data to teachers, see the chapter on Conversation-Based Assessment (CBA; e.g., Jackson and Zapata-Rivera, 2015; Lopez et al., 2017, 2021) in this Encyclopedia. This example highlights the gap between what LA researchers may think is important based on literature and what teachers perceive as needed in the classroom.

Incorporating this information into dashboards requires a good understanding of Human-Computer Interaction, a field focused on how people interact with computer operated machines, to ensure the human knows what to do during interaction. With the help of LA, dashboards have provided information necessary for many students to see their progress in open learner models (an important area in the field; see Bodily et al., 2018). Perhaps the adaptive diagnostic formative assessment system ASSISTments (Heffernan and Heffernan, 2014) has the most notable dashboard as teacher promotion has been the driving force of the mass level adaptation of student use of this free system (over half a million since the onset of COVID-19) and cited in external evaluations as an extremely effective system that met the challenge of aiding students in need (Barshay, 2021). Teachers can see on a sub-skill level what their students understand on an individual and classroom level (Zapata-Rivera and Katz, 2014) and have additional control to assign assignments, researcher created interventions, and display of reports in classes to guide class instruction without embarrassing one student. The developers of ASSISTments accredit their ability to listen to teachers input, thus keeping teachers in the driver's seat of this both adaptive (controlled by the computer) and adaptable (controlled by the teacher) digital environment as the reason for their great success (Heffernan and Heffernan, 2021; Murphy et al., 2020; Sahni et al., 2021).

These are just a few applications of LA. To be clear, LA and ML are not always implemented together. However, if one is new to LA, it may be useful to understand the various types of ML algorithms often used. Therefore, we provide a primer below.

Machine learning in learning analytics

The discipline of Machine Learning (ML) focuses on constructing computer systems and algorithms that automatically improve in accuracy through experience. Although ML has been an active field of research since the 1950s (see Samuel, 1959 for the implementation of ML in the game of checkers), the increased use of technology and resulting data has created opportunities for these algorithms to address numerous practical problems. Education has seen a similar growth in digital learning and assessment technologies over the past 30 years. ML is a primary set of analytic tools used within LA to analyze data resulting from these complex digital learning and assessment environments (Baker and Yacef, 2009; Hernández-Blanco et al., 2019; Romero and Ventura, 2020; Salloum et al., 2020). We review the main types of ML algorithms by providing examples from the field of education to explain how these methods work.

In traditional software engineering, programmers distill knowledge into computer code which instructs the computer to perform specific processes based on input to generate the desired output. In ML, rather than have a human author the computer program, the human provides the computer machine learning algorithms together with training data (i.e., data examples) to identify an optimal computer program that learns from the training data and produces the desired behavior according to a specific metric (e.g., performance). Take, for example, the task of learning to detect whether a student is engaged (or focused on the task) or distracted in a digital reading exercise (such as described in the Section [Behavior modeling](#)). It may be hard to build a software program to detect engagement. However, a human expert (such as a trained researcher) may be able to provide examples of students who are engaged and distracted. These examples can be decomposed into a set of inputs from the corresponding log files (i.e., features) for the ML algorithm. These features might include information like how quickly students were scrolling in their reading task, how often they spoke to their classmates, how many times they looked away from the screen, or even capture more low-level data like computer logs generated by the reading task. With the help of each of these examples, the ML algorithm produces an output (i.e., label), such as "engaged" or "distracted". The number and types of examples the teacher provides the ML algorithm are called *training data*. Through the training data, the system may learn a specific set of features that predicts engagement. Researchers have developed a large array of ML algorithms to handle different constraints and challenges and these methods have been leveraged and adapted within the field of LA to support student modeling, adaptation and recommendation, feedback, and assessments. These algorithms can vary in terms of: (a) the type of program or knowledge the system can learn, (b) how the algorithm represents that information, and (c) the requirements surrounding the training experience. Distinguishing these algorithms in terms of their training experience

Table 1 Examples of research that use similar classes of ML algorithms across different LA applications.

LA challenges		ML approach	Examples
Student modeling	Supervised	Logistic regression models, markov process models, recurrent neural networks	Gervet et al. (2020)
	Unsupervised	K-means, hidden markov models	Sharma et al. (2020)
	Reinforcement learning	Inverse reinforcement learning	Yang et al. (2020)
Adaptation and recommendation	Supervised	Recurrent neural networks	Pardos & Jiang (2020)
	Unsupervised	Pairwise constrained K-means	ALSaad & Alawini (2020)
	Reinforcement learning	Multi-armed bandit algorithms	Li et al. (2020)
Feedback and score reporting	Supervised	Random forest classifiers	Cavalcanti et al. (2020)
	Unsupervised	K-means	Li and Paquette (2020)
	Reinforcement learning	Deep reinforcement learning, deep Q Networks	Ju et al. (2020)

Note: We highlight recent studies from the 2020 Proceedings of the International Conference on EDM and the Learning Analytics and Knowledge (LAK) Conference.

requirements (i.e., supervised, unsupervised, and Reinforcement Learning), we highlight studies that demonstrate how ML is being applied to the core research areas in the field of LA. Across these examples, we highlight the independence between the type of ML algorithm and the challenge targeted within LA, noting that often different types of ML approaches have been used successfully to tackle the same challenge in LA (see Table 1).

Supervised learning

Supervised learning approaches capture a diverse set of algorithms that take feature-label pairs as training examples (i.e., correct answer is given as feedback) and submit these to a program for generating a label for a set of features that are not in the training examples. Supervised classifiers can learn to predict discrete labels (e.g., classification) or continuous outputs (e.g., regression). We previously described a binary classification problem of detecting whether a student was “engaged” or “disengaged”. Supervised learning approaches provide an optimal solution to this problem as these algorithms “learn” different types of and numbers of label predictions based on a dataset where labels are identified by human experts. During this process, it’s possible a human expert identifies someone as not only engaged but also confused. This challenge is met with algorithms that support multiclass classification (e.g., more than two labels) and multilabel classification (e.g., each input can be associated with multiple labels). Regression based classifiers then can learn the function that approximates the mapping between input variables (e.g., engagement and confusion) and some continuous output variable (e.g., learning).

Supervised approaches can vary in terms of the complexity of programs. Deep learning approaches, such as artificial neural networks use complex multilayer networks of nodes that each learn a simple function when trained on feature-label pairs. When unlabeled data is provided to a trained model, the combination of these functions produce a label prediction. These approaches can be especially useful when working with large input features sets (such as pictures and videos). In educational context, Jiang et al. (2018) demonstrated how a neural network-based approach could be used to successfully classify the affect and behaviors of students, comparing a set of neural network-based approaches to regression-based supervised learning approaches. Both types of supervised approaches were trained with labels generated by humans observing a student’s affect during the class session using the BROMP assessment paradigm described earlier (Ocumpaugh et al., 2012, 2015). However, the regression-based approach required human-labeled features whereas the neural network based approach only processed raw computer logs as input. In discussing their results, the authors highlight the trade-off between these two types of supervised classification approaches. Specifically, they point out that although neural networks can derive meaningful features from the raw interaction data, the representation of the relationship between these features and specific student states is too complex to interpret creating a lack of transparency and interpretability. On the other hand, the regression-based approaches required additional steps from humans which can be time consuming and expensive to generate the features; however, the representation that these models learn lends itself to generating psychological or educationally plausible explanations for why certain features are associated with certain student behaviors.

Note that not all supervised algorithms that require a large amount of human effort represent knowledge in a way that is easy to introspect. This directly impacts the interpretability of its outcomes. For example, Decision Trees have a tree structure that organizes labeled data according to a series of sequential decisions; therefore, it is easier to interpret the output of a Decision Tree. However, Decision Trees have some drawbacks, such as efficiency of its algorithms, overfitting, and its predictive power compared to other ML algorithms (Ali et al., 2012). Random Forests (Breiman, 2001), which are an extension of Decision Trees, overcome above-mentioned drawbacks with a tradeoff with the interpretability of their outcome. However, it is possible to increase the interpretability of this type of so-called “blackbox” ML models (i.e., models where it’s difficult to interpret what exactly is occurring because the inputs are unknown). For example, Hutt et al. (2018) used different classifiers (e.g., Random Forest, Gradient Boosted Decision Tree, Logistic Regression) to predict whether students would graduate college based on features from their college applications. The Random Forest classifier outperformed other types of more interpretable classifiers (Gradient Boosted Decision Tree, Logistic Regression) and achieved a predictive accuracy of 71.4%. The authors combined several approaches to

determine a minimal feature set and feature selection (i.e., stochastic hill-climbing approach and logistic regression) to gain insight into what features of a student's application contributed the most to the classifier's performance. Although this type of approach can help to understand the correlation between the features and the outcome variable, the authors concluded that future work combining top-down feature encoding approach together with bottom-up approach could help to illuminate causal relationships beyond correlations.

Unsupervised learning

Unsupervised learning includes a suite of methods for identifying patterns within the input features without the guidance of output labels. These approaches can be used to identify important trends in the input data and generate the output labels for unlabeled data (identification of important features in the log data). These types of approaches are especially useful for problems in which the outcome is difficult to label or represents a probabilistic state (e.g., where there is uncertainty surrounding output labels). Unsupervised clustering approaches learn "latent" (e.g., missing) labels through identifying categories within the set of training objects. These categories reflect structures or patterns present within the data.

For example, [Mostafavi and Barnes \(2017\)](#) used hierarchical clustering, an unsupervised learning method to discover different strategies when students were solving particular problems presented in an intelligent deductive logic tutor. The authors created a data-driven problem profiler, which used the hierarchical clustering of exemplar scores of students who interacted with the tutor in the previous semester to identify different student profiles (i.e., clustering students based on their application of specific Knowledge Components throughout the tutor). This allowed for their system to identify students that use distinct strategies for solving problems within the tutor and adapt the system to provide appropriate support. In addition to providing valuable descriptive information about the student, [Mostafavi and Barnes \(2017\)](#) describe how data-driven clustering can improve how accurately the system could determine student proficiency. This purely data-driven approach was not able to predict student proficiency more accurately than proficiency based on an expert-based approach. However, unlike an expert approach, the data-driven approach could be easily scaled to support greater numbers of students without the needing significant human input.

While this example highlights one application of unsupervised learning to identify groups of students, these approaches can be used across a wide variety of learning contexts to identify patterns across student behavior, student problem solving, and different types of learning content (see [Table 1](#)). The meaningfulness of the output labels these algorithms identify is largely shaped by the data submitted as input labels. For example, when profiling types of collaborative problem solvers there are numerous dimensions that need to be captured within the input data about the students working together and the way in which they interact ([Forsyth et al., 2020](#)). Without considering the corresponding social or cognitive dimensions and constructs when constructing the dataset these approaches are trained on, the unsupervised algorithm may not have the evidence needed to identify meaningful clusters of features for identifying types of collaborative problem solvers. For this reason, unsupervised clustering within LA should be an iterative process where after identification, the identified clusters should be analyzed and compared to hypotheses about the constructs or external assessments that are well-validated to determine if the output of the approach is meaningful. Without "ground-truth" student profile labels to compare the final output to, different resulting clusters can be interpreted using theory and compare resulting clusters to external surveys providing different data from the input to the ML algorithm. As with supervised learning, there is a wide range in the type of knowledge these algorithms can learn including, exclusive cluster membership (e.g., an input is associated with a single label), overlapping clustering (e.g., an input is associated with multiple labels), hierarchical clustering (e.g., labels indicate a position in a hierarchy of labels), probabilistic clustering (e.g., input features are probabilistic and there is uncertainty in how they relate to labels).

Reinforcement learning

Reinforcement learning (RL) is when the algorithm is optimized based on "feedback" from other algorithms or human interaction in the digital environment. In RL, the learning system, often referred to as an "agent", takes actions within the environment and is provided "feedback" from other algorithms or humans. Unlike supervised methods where complete examples are provided with feedback, RL agents can learn *what to do* by exploring the environment, taking actions, and receiving feedback. Take for example learning to play Tic-Tac-Toe. An untrained RL agent will take random actions within the environment. These actions will result in changes to the environment and moves by the opponent, eventually the agent will experience a win or loss. This feedback, referred to as a *reward*, helps the agent build a predictive model of the environment, its opponent, and what moves it should make in different situations. While in this learning example, reward is provided at the end of a series of actions, RL agents can also learn from throughout the learning process. As with other approaches there is diversity in how agents learn, what they can learn, and how they represent that information. Passive learning systems have fixed policies (e.g., strategies) to learn a utility function on the environment states, whereas active learning agents explore an environment and adjust the actions or rules of the algorithm in response. When developing an RL model, the researcher must consider the action space (e.g., what actions the agent can take), the state space (e.g., the representation of the environmental states), the reward function (e.g., what feedback to provide the agent), and the policy optimization (e.g., the algorithmic method for improving the agent).

RL is especially useful when learning programs/knowledge in complex domains where there are a large number of choices available making it difficult for a human to accurately evaluate all of these choices. There has been a lot of recent interest in the LA community in RL algorithms to develop guidelines for adaptation and recommendation especially within Instructional Policy optimization. In this work, RL methods explore a variety of different decisions including the scheduling of educational activities, introduction of new concepts, deciding what feedback to give, and even what class to take next (Bassen et al., 2020; Doroudi et al., 2017; Rafferty et al., 2015). In a recent example of this, Bassen et al. (2020) designed a linear algebra online continuing education course that tested the educational utility of using an RL model to schedule student's activities. The RL agents navigated the action space by choosing between educational activities. Performing these activities would change the state space, what skills the agent was estimated to know (e.g., from test scores and activity performance). Bassen et al. chose a reward function that rewarded test performance improvements and penalized the inclusion of activities covering already mastered skills which sets the ground rules for how the RL algorithm should change based on input. The researchers used data from simulated learners to train the RL agents but also updated their model with actual student data as students began to take the class. Students that were recommended activities using the schedule provided by the RL agents were less likely to drop out of the course than self-directed students and achieved comparable learning gains. While RL is well suited for the complexity of scheduling a diverse set of activities, these methods do require a considerable amount of training data to build an accurate model of the state space and suggest reasonable actions. In their paper, Bassen et al. relied on simulated learners to generate data, even so they acknowledge that it is still unclear if the approach converged. This highlights the importance of having an accurate simulation environment when training RL agents.

Trends and opportunities for the future of learning analytics

Learning Analytics and Machine Learning have been rapidly progressing in development and implementation over the last decades. Given the need for distance learning since the advent of COVID-19, we expect scientists and developers in the field to continue to push the boundaries to better aid student learning and assessment. Specifically, we highlight three areas of exciting growth within the field that use human-in-the-loop approaches: (a) theoretically-grounded educational data mining, (b) computational cognitive modeling, and (c) computational linguistic analysis and artificial agent-based interaction. For a more detailed review on the importance of human-in-the-loop approaches, see also Rosé et al. (2019) and Zapata-Rivera and Arslan (2021).

Theoretically-grounded educational data mining

Theoretically-grounded data mining (Forsyth et al., 2014) is a methodology that combines the principles of Evidence-Centered Design (ECD; Mislevy et al., 2003) with LA/EDM (Baker and Yacef, 2009). ECD is a very careful linking of pieces of evidence gathered from human interaction to higher level skills and subskills corresponding to over-arching cognitive constructs. This principled methodology has been a staple of the assessment community for decades and now more than ever is necessary for establishing the features that provide evidence of student behaviors which can inform researchers of higher-level skills as well as more abstract constructs such as collaborative problem solving. When ECD is implemented in complex digital environments, psychometrics created for traditional items such as multiple-choice items cannot necessarily be implemented appropriately, and more complex predictive modeling embodied in LA is needed. One may ask the question, why is it important to have complex environments with this level of validation required of ECD. Our answer is that we want to provide teachers and students with information that can be captured in environments designed to elicit evidence of cognition and then validated by multiple sources and even provide additional information for personalization that is grounded in theory. Without this level of scrutiny and rigor, we will not be able to substantiate claims for assessment and adaptation in learning environments and therefore are in danger of hitting a commonly scrutinized point of analysis of large log files. This criticism of EDM without ECD is that with so many variables available, spurious correlations are bound to exist (i.e., correlations that are meaningless and simply artifacts of a particular dataset) which can be addressed by combining the two methodologies (see also Goldhammer et al., 2021). After all, every level of adaptation is based on inferences from these pieces of evidence. Multiple methods for implementing theoretically grounded data mining have been proposed and can be explored (Forsyth et al., 2012, 2014, 2020).

Computational cognitive models

Computational cognitive models (CCM) are algorithmic implementations of micro theories of cognition (e.g., theories of learning, or theories of human memory) that represent fixed mechanisms of cognition together with possible free parameters to represent individual differences. Much of the research developing CCMs is based on unified theories of cognition that have been operationalized within cognitive architectures such as ACT-R (Anderson, 2007; Anderson et al., 2004), PRIMs (Taatgen, 2013), Soar (Laird, 2019). Unlike LA approaches that analyze the student log data, CCMs can simulate data (i.e., generate data) to make predictions about learner behavior without collecting data from learners (e.g., Arslan et al., 2017a; MacLellan and Koedinger, 2020). These predictions about learner behavior can then be confirmed using student data as a means of validating and improving the approach. If the model's predictions are not in line with student data, the model can be revised considering the information gathered from the data. Fig. 2 illustrates this research cycle.

Fig. 2 Proposed research cycle for using computational cognitive models within learning analytics.

While the predictive capabilities of these models have clear educational utility in testing and improving educational systems, they also offer insight into the cognitive mechanisms that underlie the observed behaviors of learners (Arslan et al., 2017b; MacLellan et al., 2016). There is potential for CCMs to contribute to research across the core areas of LA (e.g., student modeling, adaptation and recommendation, and assessment and feedback). Work within the field of cognitive science has illustrated that these CCMs can be fitted to the data to estimate the free parameters at an individual learner level and demonstrated how these free parameters can update models of student proficiency and adapt training methods to improve learning (e.g., Cranford et al., 2020; Walsh et al., 2018a). Furthermore, efforts to build models that simulate human like learning (e.g., *simulated students*) has been shown to have numerous applications within the field of LA (VanLehn et al., 1994) including authoring Intelligent Tutoring Systems at scale (MacLellan and Koedinger, 2020), providing students with opportunities to learn through teaching (Matsuda et al., 2013, 2020), and generating simulation environments to test out different instructional policies (MacLellan, 2017).

Computational linguistic analysis and artificial agent-based interaction

Computational linguistic analysis is a set of tools and procedures that support modeling the students based on the student's words. Computational linguistic analysis can help identify student understanding of material (for more details, see McNamara et al., 2017), affective states (D'Mello and Kory, 2015; Dowell and Graesser, 2014), and identify features that align to social constructs (e.g., Pennebaker, 2011) important for 21st century skills such as collaborative problem solving (e.g., Dowell et al., 2020). This information can provide rich evidence to better understand the students' thinking, motivational and affective states guiding the personalization of adaptive and adaptable components of complex digital learning and assessment environments (for a review, see McNamara et al., 2017).

An important application of computational linguistic analysis as well as theoretically-grounded data mining is the implementation of artificial agent guided learning and assessment environments. The artificial agents can be in the form of talking heads that can tutor students and dynamically adapt to these conversations. This type of work has resulted in effect sizes 0.8–2.0 compared to comparable controls in dozens of studies (for a review, see Graesser, 2016). Furthermore, these types of systems can assess students during Conversation-based Assessment and there are many other Intelligent Tutoring Systems with natural language processing including those that provide recommendations on what to do next in complex environments, which are addressed in more detail in other chapters in this Encyclopedia.

Future opportunities

While above-mentioned areas of research (theoretically-grounded educational data mining, computational cognitive modeling, computational linguistics and artificial agent-based interaction) reflect the current research efforts of the authors, we believe that they have great potential for advancing the field of Learning Analytics. The prominent theme across these areas is the emphasis of theory as the driving force behind LA and the potential refinement of these theories from the insights we draw from educational systems. Theoretically-grounded data mining and computational cognitive modeling attempt to integrate theory with analytics including ML in an iterative fashion to increase the validity of findings and ensure transparency and interpretability via an interdisciplinary approach. Computational linguistics and artificial agent-based interactions focus on understanding human words to interpret the underlying knowledge and state of the human for adaptation based on the human's needs. Agents can add to this endeavor by interacting with students in a manner that mimics a personalized tutor or peer for the purposes of optimal learning. We acknowledge that many more applications of ML and LA may also make great contributions to the field and encourage researchers to explore these areas while considering how these topics can provide a lens through which we can build a better understanding of human learning.

Conclusions

We began this chapter with a vision of a future in which personalized learning affords universal access to the highest quality education. While this future is still distant, research within the field of Learning Analytics has demonstrated a path to this future. In recent years, Machine Learning has featured prominently within the community as a powerful tool through which we can translate data into insights, approaches, and systems for supporting learning and assessment.

We provide a general introduction to three major areas of research within LA and discuss where the application of ML has advanced these research areas. The primer on applications of LA discusses a variety of student modeling or attempts to understand the student's current state or level of knowledge to inform algorithms for personalizing instruction to a student's needs. We discussed modeling based on student knowledge where the algorithms (e.g., Bayesian Knowledge Tracing; for more details, see Pelánek, 2017) adapt based on the student's performance on previous items to inform the computer program to present material that is best suited to the students current understanding of the material. Another type of student modeling discussed is based on the student's behavior and current state. This type of modeling allows for adaptation based on detected affective states or other corresponding states within the learning experience which can increase student learning (D'Mello, 2017). The applications of LA for student modeling include adapting the computerized system for personalized support as well as providing computerized feedback by a computer or arming a teacher with needed information for individual and classroom level interventions.

The primer on ML discusses three common types of modeling including unsupervised learning, supervised learning, and Reinforcement Learning. Unsupervised learning requires minimal human input and allows for the algorithm to determine the human state whereas supervised learning requires human tagging of information for input to the algorithm. Reinforcement Learning algorithms have been used more recently to aid the computer in adjusting algorithms for optimal strategies. These three models are staples within the LA community but it is important to note that ML is not synonymous with LA but rather tools to interpret student state or knowledge and then adapt accordingly for optimal learning.

Our main purpose of this article was to outline how LA and ML can contribute to student learning now more than ever. Given the pandemic and associated equity issues, adaptation comparable to human tutoring is necessary for "closing the gap" in education (Heffernan and Heffernan, 2021). This gap refers to a long list of inequities that have been exacerbated by the pandemic such as differences in socio-economic status that may result in some students having access to internet whereas others do not, access to books, and parents with advanced degrees with time to help their children versus parents that must work outside the home and may or may not have the education to help their children. There are many potential facets, many likely yet to be discovered that have created a myriad of educational experiences for students during this unique time in history including geographical location and school funding situations. This brings us to one final potential use of LA which is to potentially identify students based on groups of features affecting post-pandemic education and determine the best intervention(s) to help affected students. Furthermore, LA often with carefully applied and interpretable ML techniques has laid the foundation for students to receive personalized learning experiences that adapt based on student's knowledge and states. Thus, appropriate applications of learning analytics may be more important now than ever before in history.

In the overarching realm of educational measurement, the collection and analysis of data in order to gather knowledge about students' skill sets and their learning progress has always been of focal interest for educational stakeholders (OECD, 2013, 2017). This is particularly the case since such data have several implications that can shape students' future educational trajectories. For instance, a student's grade point average (GPA) to a large extent determines whether they are allowed to advance in their educational journey or are required to repeat a class or even an entire grade (e.g., Huebener and Marcus, 2017).

However, teachers, parents, and students themselves are not only interested in data indicating a passing or failing score in a particular subject or the GPA. Instead, data on factors that contribute to one's chances of meeting—or falling short of meeting—the standards required to achieve educational progress carry comparatively more fine-grained and thus crucially valuable information. Such data may include the time spent on individual learning exercises or the number of interactions made when working on a computerized training program focusing on the acquisition or refinement a specific skill (i.e., computer-based process data).

Such computer-based process data include all information collected during a student's interaction with a given computer program, ranging from time spent and number of clicks made on a particular page to the number and content of questions asked to a virtual tutor in a computerized learning simulation (Goldhammer et al., 2017). We will now provide an overview of the contents of this article, which, in brief, centers on the characteristics, history, contemporary use of process data analysis in educational measurement, a concrete example, and future challenges and directions in order to advance educational policy and practice.

Facets of computer-based process data analysis in educational measurement featured in this article

In this article, we first address the question of what computer-based process data are and illustrate their relevance for the educational measurement context (Section **The role of computer-based process data in educational measurement**). Thereafter, in **History of computer-based process data analysis in educational measurement** section, we present the historical evolution of computer-based process data analysis in educational measurement from its inception to its widespread use today. Subsequently, the availability of public computer-based process data repositories and the importance of computer-based process data in large-scale educational assessments will be described (Section **Public computer-based process data repositories**). In **The current state of computer-based process data analysis** section, we discuss the current state of computer-based process data analysis in educational measurement in greater depth with regard to three central facets: (4a) psychometric models; (4b) formative assessment; and (4c) summative assessment. Psychometric models are included as they serve as the statistical backbone for the thorough and valuable analysis and interpretation of computer-based process data in the educational context (particularly with regard to valid and reliable student assessment; DiCerbo et al., 2017; Mislevy et al., 2012). Meanwhile, formative and summative assessment represent today's two most widely used assessment techniques for monitoring students' learning progress, and have at the same time become a hallmark

of evaluating and advancing educational practice (Gallardo, 2021; Harlen, 2011). Thereafter, in **Applied computer-based process data analysis in educational measurement: the example of complex problem solving** section, we provide an in-depth showcase of applied computer-based process data analysis in educational measurement by referring to the skill complex problem solving, which has been shown to be a key competence for students' educational success and beyond (Mainert et al., 2015; Schweizer et al., 2013). The article concludes with a summary of the relevant aspects of educational computer-based process data analysis and some final thoughts on current challenges and potential future directions for computer-based process data analysis in the educational measurement context (Section **Summary, challenges, and future directions of computer-based process data analysis in educational measurement**).

Notably, this article aims to present a thorough overview and theoretical background of process data analysis in educational measurement, and to provide indications for interested researchers and students on exemplary deeply vetted resources facilitating individual process data analysis endeavors. However, due to the vast amount of theory, practical aspects, and considerations involved in computer-based process data analysis, it is unrealistic to assume that this article provides information on each and every nuance of process data analysis in educational measurement. Therefore, we will at times point the interested reader to further in-depth scholarly sources, such as journal articles or books, about specific phenomena in educational process data analysis. Where applicable, these suggestions are given at the end of each respective section.

The role of computer-based process data in educational measurement

Computer-based process data are automatically stored in computerized log files (Zoanetti and Griffin, 2017) that contain raw information on each action a student performs with a software (e.g., a task or an exercise; see Fig. 1). Compared to other well-established types of process data in educational measurement research, such as think-aloud protocols or eye tracking (Branch, 2001; Horstmann et al., 2009), computer-generated process data are generally collected in a less "invasive" way while a student performs different actions on a computer; that means, the student is typically not explicitly aware of being monitored (Adams et al., 2015). In this regard, the generation and collection of such computer-based process data in digital gamified learning environments (i.e., educational game software) has also been termed "stealth assessment" (Shute, 2011; Shute et al., 2016b). The ability to automatically log computer-based process data in such a non-interfering way is a particularly valuable asset, since students' subjective reports of their perceived skill levels can be susceptible to bias and inaccuracy, as they put additional demands on the student and could interfere with actual processing of the task (e.g., Brown et al., 2015).

The thorough scrutiny of the vast amount of computer-based process data inherent in such log files (i.e., computer-based process data analysis) is typically referred to as data mining, which comprises various steps in order to arrive at data that is ready to be interpreted (Aldowah et al., 2019; Ali, 2013). As this process is generally complex and requires advanced methods, time and computer programming skills, it is usually performed by (semi-) automated programs provided by experts in the field (Gobert et al., 2013; Romero and Ventura, 2007, 2020; Slater et al., 2017). Importantly, these programs are tailored to produce the pieces of information desired for a given purpose, such as universities looking into reasons why students drop out of a given study program or teachers trying to uncover the reasons for their students' poor test results (Hsia et al., 2008; Mostow et al., 2005).

Fig. 1 Part of a raw log file in .xml format containing process data depicting the actions applied by a student during a complex problem solving task (see also **Summary, challenges, and future directions of computer-based process data analysis in educational measurement** section and Fig. 2 of this article) in a computer-based large-scale assessment in Finland. Based on Vainikainen (2014).

History of computer-based process data analysis in educational measurement

The computerized administration of not only tests but also classroom learning exercises has become increasingly common since the late stages of the 20th century (Bunderson et al., 1989). This trend continues to be observed today (Danniels et al., 2020). Accordingly, the mid-1990s mark the inception of the first research articles referring to the use of computer-based process data to evaluate and improve policies in educational institutions (for an overview on data mining in the educational context between 1995 and 2005 see Romero and Ventura, 2007). One of the first articles explicitly using the term “computer-based process data,” albeit in an organizational context, was published by Langley (1999). Soon thereafter, further researchers began scrutinizing computer-based process data from different types of log files for educational purposes (Srivastava et al., 2000), leading to rapid growth of the field. One of the earliest published computer-based process data analyses presents algorithms used to thoroughly map a variety of student characteristics (e.g., courses taken and credits earned in different disciplines) in order to more efficiently allocate staff and resources in educational institutions (Luan, 2002). Other pioneering studies address the leveraging of computer-based process data from digital learning and communication platforms for uploading presentation slides and exercises, submitting reports, and directly asking questions to peers and teachers (Mazza and Milani, 2005; Mostow, 2004; Paulsen, 2003).

The aforementioned selection of different ways to investigate and use computer-based process data for educational purposes further expanded over the first decade of the 21st century. During this period, studies began to focus on particular benefits for both students and educators, such as improving communication and adapting curricula by clustering and classifying students into different groups, for example (Romero and Ventura, 2007). A comprehensive overview of the most influential papers in the early years of computer-based process data research can be found in Baker and Yacef (2009).

At around the same time, the educational data mining sub-field known as process mining emerged, which focuses on the analysis computer-based process data (i.e., log files) with the aim of improving existing processes, or skills, in a variety of domains, from workers’ deadline management in organizations to how people book vacation lodging online (Van der Aalst et al., 2010). While initially primarily targeted at business process models (Van der Aalst, 2012), process mining was rapidly extended to the educational domain. Existing research in this vein draws upon computer-based process data collected from students watching different educational video sequences, or from their interactions with digital learning platforms, in order to adapt said videos and platforms accordingly (Bogarín et al., 2014; Van der Aalst et al., 2015). Similar research has been conducted to increase the appeal of computer-based training programs based on inferences about people’s motivation to take part in such programs drawn from computer-based process data (Cairns et al., 2015). Moreover, contemporary research investigating computer-based process data has targeted the evaluation and improvement of a variety of additional educational measurement facets. As such, recent research articles examine interactive learning environments, different assessment approaches, and individual students’ skills that have been shown to be particularly related to educational success, and not seldom make use of publicly available computer-based process data repositories for their analyses (Cerezo et al., 2020; Greiff et al., 2015; Nicolay et al., 2021).

In sum, it can be seen that computer-based process data analysis for educational purposes has become more “fine-grained” in the last 15–20 years. In fact, an increased specialization of individual process data analyses has primarily been made possible due to technical advancements allowing researchers to capture the desired processes accurately using increasingly powerful computers and software (Adjerdj and Kelley, 2018). Additionally, the availability of public process data repositories has put increased amounts of more easily accessible data at the disposal of both researchers and educational stakeholders.

Public computer-based process data repositories

Nearly simultaneously with the widespread recognition of the scholarly potential of computer-based process data analysis, researchers became particularly interested in using such data to improve educational practice (e.g., Branch, 2001). Initially, scientists engaging in computer-based process data analysis largely had to work with their own datasets. However, around 15 years ago, the first public computer-based process data repository was established, creating a new possibility for researchers to carry out computer-based process data analysis without being forced to collect their own data, and easing the comparison and verification of published results (Koedinger et al., 2008). At the same time, research began to increasingly rely on data from digital learning environments used for communication among teachers and students (Baker and Yacef, 2009).

Currently, several public computer-based process data repositories from different sources exist. We want to showcase two contexts of data sources, which are frequently employed by researchers.

First, numerous public repositories for computer-based process data exist from *online tutoring systems* (e.g., “ASSISTments,” “DataShop,” “vMS-Share,” “KEEL”). These repositories are continuously growing, are freely accessible to researchers all over the world, and provide data from people’s interactions with computer-based systems across multiple domains, either in their raw log file format, or in item-level responses per individual participant. Given the amount and variety of available data, these public repositories represent a crucial resource for the advancement of educational policy and practice (Alcalá-Fdez et al., 2011; Blonder et al., 2019; Feng et al., 2009; Koedinger et al., 2010).

Second, data from international large scales assessments (ILSAs) represent another valuable source for data mining. The two presumably most widely known ILSAs “Program for International Student Assessment” (PISA) and “Program for the International Assessment of Adult Competencies” (PIAAC) offer great insights into (educationally) relevant competencies, including reading ability, numeracy, or innovative competencies, like problem solving, among both school students (PISA) and adults (PIAAC) across the globe. Some of these competencies are assessed with computer-based assessments and thus, are stored in computer-based process data (Jude, 2016; Kirsch and Lennon, 2017). As the logged process data of both assessments are publicly available on the official website of the Organization for Economic Co-operation and Development (OECD; see <https://www.oecd.org/pisa/data/> for PISA, and <https://www.oecd.org/skills/piaac/data/piaaclogfiles/> for PIAAC), it is not surprising that multiple studies have used these data for fine-grained analyses of students’ and adults’ educational achievement (Goldhammer et al., 2020; Greiff et al., 2015; He et al., 2017; Liao et al., 2019; Teig et al., 2020). For both assessments, the process data are both available in raw log file format, and in item-based responses per country. Thus, it can be seen that the computer-based process data stored in the publicly available data repositories for PISA and PIAAC represent a valuable resource for scholars to learn more about how both students and adults interact with digital environments as well as their skills in key educational competencies.

The current state of computer-based process data analysis

Having provided a thorough overview of the purpose, history, and application of computer-based process data analysis in educational measurement, and introducing some of the most relevant publicly available computer-based process data repositories, we will now discuss the current state of computer-based process data analysis. In this regard, we will focus on three major facets of computer-based process data analysis due to their importance for successfully conducting and drawing valid inferences from computer-based process data analysis: (a) psychometric models (see 4.1), (b) formative assessment (see 4.2), and (c) summative assessment (see 4.3). In brief, psychometric models serve as statistical foundations for computer-based process data analysis. Formative assessment refers to the evaluation of students’ learning progress during a particular learning exercise or course, while summative assessment measures students’ learning progress after the learning exercise or course has been completed.

Psychometric models

Psychometrics can be defined as “the science of psychological assessment” (Rust and Golombok, 2014, p. 4) and is concerned with how psychology research measures designated phenomena to arrive at meaningful conclusions (Jones and Thissen, 2006). Computer-based process data pose several challenges for psychometric modeling that should be highlighted before moving on to psychometric models that have been specifically developed to deal with these challenges (Mislevy et al., 2012).

Firstly, computer-based process data differ markedly from “traditional” data (i.e., data that were not collected automatically via a digital entity during an assessment process). Such “traditional” data are usually limited to an absolute preference or performance score obtained from each individual participant over a given number of items. For instance, when analyzing such “traditional” data, it is nearly impossible to detect a learning effect for a participant over the course of multiple assessment items apart from a potentially higher overall success rate. Computer-based process data, on the other hand, might detect such a learning effect not only in the form of higher overall performance scores, but also using other indicators like consistently lower response times or fewer intermediate errors committed over several items.

Secondly, logged process data are not limited to a particular type of data such as responses on a Likert scale or number of items correctly recalled from memory. Instead, a single log file contains numerous data points in various formats, such as written information the participant typed, time stamps indicating when the participant started and completed a task, and the exact times and instances the participant clicked on each button shown on the computer screen. Therefore, compared to traditional data, computer-based process data pose unique challenges for psychometric models due to their fine-grained nature.

Today, however, a variety of different psychometric models (i.e., statistical frameworks aiming to explain how data are generated and can subsequently be analyzed in a valid and reliable manner; American Psychological Association, 2020) suitable for computer-based process data analysis are available that seek to address these challenges. One example is the evidence-centered design (ECD) framework, which has received increasing attention for computer-based process data analysis in the educational context (Mislevy et al., 2003). The ECD framework encompasses several different parts. The *student model* consists of the variables to be measured, while the *task model* refers to the situations in which these variables can be observed. Notably, the psychometric model, together with evidence identification rules, serves as a link between the two former models, creating a final evidence model. Based on this ECD framework, Levy (2020) identifies the four psychometric categories of preparing data, analyzing data, presenting data, and situating the work in each of these three categories. In order to account for the varying nature of computer-based process data, Levy (2020) argues that the interdependency between such process data (indicative of a person’s behavior during the task completion process) and product data (an end result or performance score after task completion) needs to be considered. This can be accomplished, for instance, by adding variables from the student model in order to distinguish factors related to the process from those constituting the product, and additional related techniques (p. 223).

Next to the ECD, the Extended Learning and Assessment System (XLAS) framework (Von Davier et al., 2019) represents a second psychometric model for computer-based process data. The developers of this framework argue that the three dimensions of *assessment*, *learning*, and *navigation* must be considered when working with multimodal data such as computer-based process data. They additionally emphasize that, when trying to recover information from computer-based process data, how to extract and create meaningful results from initial raw and unorganized bunches of data should be prioritized.

In addition, Kroehne and Goldhammer (2018) propose using finite state machines to extract the desired data points from initially cumbersome-to-analyze log files. Such finite state machines act as a measurement tool of how the participant interacts with the computer during a specific part of the overall assessment; thus, they act as encoders of the information stored in a given log file. This specific part (e.g., one item within a large questionnaire) represents the finite state, which can be defined theoretically a priori, but also changed later on—for example, to achieve comparability with other assessment approaches incorporating similar action sequences. Importantly, participants' behavior as they progress through this collection of subsequent finite items can then be investigated not only on the within-person level, but also across the different items. Kroehne and Goldhammer (2018) illustrate this procedure using computer-based process data from PISA, discovering that their finite state machine approach produces valid results.

Taken together, although the complexity of computer-based process data poses a unique challenge for researchers, several psychometric models are currently available to facilitate scholarly work with such data. Indeed, psychometric model approaches such as XLAS, ECD, and finite state machines represent valuable tools for both educational stakeholders and scholars. Importantly, as psychometric models are generally based on a theoretical foundation, they are only as useful as their underlying theory. Thus, a strong and well-established theory serves as the best precursor for the development of a meaningful and useable psychometric model (Rupp et al., 2012; Zehner et al., 2020). Consequently, building one's psychometric model on a sound theoretical foundation crucially facilitates formative and summative assessment of students based on computer-based process data (Drachler and Goldhammer, 2020; Zhu et al., 2016).

Formative assessment

Evaluating students' learning progress by means of different assessment techniques has always been an integral part of educational measurement. Nevertheless, formative assessment has received increasing attention in education since the beginning of the 21st century (e.g., Bell and Cowie, 2001). Formative assessment entails the evaluation of students' learning in order to adapt learning policies (e.g., curricula) both on an individual level as well as on a broader class or school level (Van der Kleij et al., 2015). Formative assessment practices are widely known as "assessment for learning" and typically performed during the course of a learning activity or semester rather than afterward, as is the case for summative assessment (Saeed et al., 2018; see 4.3). In addition, a core purpose of formative assessment is to support students' learning by giving and receiving feedback. This feedback does not inherently center on monitoring a student's progress with respect to the learning content, but rather seeks to provide suggestions for improvement with regard to a student's learning strategies (Gikandi et al., 2011). Furthermore, formative assessment can also be computer-based (Bergeson, 2019; Wijesooriya et al., 2015). As such, it can be put into practice by asking students to carry out a classroom task in several smaller groups, for example, and subsequently having the students provide feedback to their peers in the same group. This not only allows students to point out aspects of tasks their peers are approaching differently, but also directly engage in a discussion about how these different learning strategies might be more or less likely to (in)efficiently lead to (in)correct results. Moreover, such discussions can increase students' knowledge about learning strategies and their flexibility in applying and adapting them. Overall, formative assessment represents an important complement to summative assessment, as it can significantly help students achieve higher performance scores in summative assessment tests (Harlen, 2011; Zheng et al., 2019).

The analysis of computer-based process data from formative assessment contexts is spurred by its increasing relevance in educational contexts. Several studies have developed digital learning environments that provide feedback to students throughout their interaction with the environment, while simultaneously yielding a rich set of computer-based process data. For instance, analyzing computer-based process data from the personalized e-learning system PELS, which specifically tailors the content and frequency of feedback to a student's individual needs, revealed a significant increase in students' mathematical abilities after completing learning sessions in the digital learning environment involving more immediate feedback (Chen and Chen, 2009). Similar results were obtained for a related program in the field of mathematics called MATHia, which students used over the course of an entire school year (Zheng et al., 2019). In their study, Zheng et al. (2019) analyzed the computer-based process data employing different statistical models, which produced different results. Thus, the authors emphasize the importance of specifying the statistical methodology of choice in a given context prior to diving into a fine-grained investigation of computer-based process data (e.g., cluster analysis versus hierarchical modeling; Miller et al., 2015). Likewise, researchers should carefully consider how to use and interpret student scores obtained from computer-based process data in order to ensure the validity of formative assessments and their results (Hopster-den Otter et al., 2019).

Alongside established school subjects such as mathematics, domain-general 21st century skills (i.e., skills such as complex problem solving that have been identified as especially relevant for today's learners; Trilling and Fadel, 2009) have been located at the core of digital learning environments producing computer-based process data. In this regard, an analytical framework has been established addressing how to immediately provide feedback to students while they are still working on a given task (Choi and Cho, 2020). This allows students' learning paths to be modeled in more depth, tracing not only the final result of a particular

task, but also the individual steps the student took to arrive at this final result. Moreover, [Choi and Cho \(2020\)](#) analyzed the computer-based process data from their formative assessment methodology by contrasting the observed learning trajectory of individual students to a predefined expected learning trajectory at several time points during a task. This allowed the specific time points at which feedback should be provided to students to be identified, leading to improved feedback timing and content ([Choi and Cho, 2020](#)).

Summative assessment

At present, the most widely applied assessment technique in Western classrooms is summative assessment ([Saeed et al., 2018](#)). Summative assessment refers to assessing students' learning outcomes once at the end of a course in order to make decisions about the students' ability to transition to other courses or the next grade level ([Anthony and Susan, 2005](#)). **Table 1** can help readers understand the differences between formative and summative assessment at a glance.

One example of summative assessment in practice is to require university students to complete a final exam in an introductory module at the end of the semester, and subsequently using each student's score on this final exam to determine whether they are permitted to enroll in the advanced module next semester. In general, summative assessments are deployed for purposes at the individual student level, such as admissions, ability grouping, grading, norming, or mastery of a particular subject ([McGarr and Clifford, 2013](#); [Van Groen and Eggen, 2020](#)).

Multiple research studies have already used computer-based process data analysis to shed light on factors influencing students' summative assessment results. For instance, [Aojula et al. \(2006\)](#) compared the results of a computer-based summative assessment of undergraduate students to teachers' marking by hand and to the results obtained from multiple-choice marking machines that read students' answer sheets. They demonstrate that using computer-based process data analysis represents a viable and beneficial alternative to traditional summative assessment modalities, given its higher practicality and accuracy (e.g., the results are provided directly and automatically and do not need to be calculated by hand). Furthermore, [Gocheva-Ilieva et al. \(2020\)](#) employed common data mining techniques such as cluster analysis to evaluate the impact of different elements of the summative assessment approach on students' final grades in mathematics, discovering a significant influence of students' sex and selected elective subjects. Likewise, computer-based process data from a large-scale summative assessment in France were used to examine the potential benefit of students' employment of strategies such as trial and error versus a planned, structured approach when solving a computer-based mathematics problem ([Salles et al., 2020](#)). The authors concluded that although neither of the two strategic approaches resulted in better or worse overall performance, all students could validly be classified into one of the two strategy groups using the employed cluster analysis. Another recently published study presents the assessment program Winsight[®], which targets potential improvements in individual summative assessment components (e.g., by providing information about students' proficiency and ensuring full accessibility for students with disabilities or limited knowledge of the language of instruction) in order to foster student learning ([Stone and Wylie, 2019](#)). The program primarily seeks to funnel such information to educational stakeholders such as school headmasters and curricular decision-makers. The authors apply their new approach using computer-based process data analysis in order to assess test accessibility (i.e., how different populations of students navigate through the test, select and refine their answers) and thus provide good validity indicators for their assessment program.

In sum, we have seen that caution is advised when analyzing computer-based process data to ensure that valid, meaningful and interpretable results are obtained that carry useful implications for education. However, when suitable statistical methodology and psychometric models capable of accurately capturing and presenting the desired information are applied, computer-based process data analysis represents a valuable tool for the advancement of both formative and summative assessment practices. This includes but is not limited to providing feedback about and evaluating students' learning trajectories.

Table 1 Overview of the purpose, administration, usability, and examples of formative and summative assessment in education.

	<i>Formative assessment</i>	<i>Summative assessment</i>
Goal	Providing feedback and facilitating learning and instruction	Assessing students' knowledge of a particular subject or domain
Time of application	During a learning exercise or course	After a learning exercise or course
Use for teachers	Evaluating students' learning methods and the quality of the learning material, adaptation of exercises and curricula	Understanding individual and class performance, comparing scores to other schools, grading
Use for students	Assessing one's own learning methods in relation to peers, self-evaluation	Evaluating one's own progress in relation to peers and curricular standards
Examples	Self-tests, practice exam	Final exam, individual report

Applied computer-based process data analysis in educational measurement: the example of complex problem solving

At this point, having presented a general overview of the current state of computer-based process data analysis in educational measurement, we would like to illustrate how computer-based process data analysis can be used in practice to fill knowledge gaps regarding how students apply a skill that has been shown to be particularly relevant for educational success and beyond: the domain-general 21st century skill complex problem solving (CPS).

CPS skills can be defined as the ability to solve problems that possess unique features, such as hidden relationships between variables, multiple goals to be reached simultaneously, and the potential for variable values to change dynamically at any given time during the solution process (Greiff et al., 2013a,b). One example of a complex problem could be trying to use a recently updated self-service ticket machine to purchase a train ticket, an example that has already been used in PISA (OECD, 2014; here CPS was labeled as creative problem solving). In order to ultimately make the correct purchase, it is crucial to apply a strategic approach (i.e., deliberately clicking on different buttons on the machine) to build up one's knowledge instead of performing random clicks (i.e., applying the vary-one-thing-at-a-time or VOTAT strategy, also referred to as the control of variables or CVS strategy; Schwichow et al., 2016).

Computer-based microworlds have become the current standard for assessing students' CPS skills (e.g., Stadler et al., 2015). These microworlds involve different hypothetical scenarios as complex problems that must be solved, such as creating a lemonade using different ingredients with arbitrary labels or evaluating the impact of changing the dosage of several unknown types of medication on different body functions (Greiff et al., 2013a,b). In CPS assessment, students can explore the initially hidden relationships among the variables within a given item by moving sliders and clicking different buttons. These actions, as well as others, can be used for process data analysis. See Fig. 2 below for an exemplary CPS item.

Fig. 2 A complex problem microworld involving multiple variables with hidden relationships (see also Fig. 1 in The role of computer-based process data in educational measurement section for a corresponding log file containing process data). After the variable relationships have been discovered in the problem space (top part) by applying strategies such as VOTAT, the student is asked to indicate each present relationship in the model space (bottom part).

Importantly, computer-based process data are collected and stored in log files while students work on the complex problems within such a microworld. These log files capture all relevant components of a student's interaction with a given problem, including time spent on an item, all variable manipulations and their corresponding time stamps, and whether the student achieved or at least approximated the predefined goals (Xu et al., 2018). A common approach to extracting valuable information from this computer-based process data after CPS assessment is to write an automated program that iterates through all log files and parses the relevant data points for further subsequent statistical analyses. For instance, if data are stored in XML-format, this can be achieved using so-called XML parsers (i.e., programs that automatically extract the desired information from raw log files; e.g., Appen and McDaniel, 2009).

The importance of CPS for both educational and career success as the ability to manage novel and dynamic situations in a systematic way has been discussed in multiple studies (Schweizer et al., 2013; Wüstenberg et al., 2012). Thus, it does not come as a surprise that a large body of research on CPS using computer-based process data from large-scale assessments, including PISA, has accumulated in recent years (Greiff et al., 2015; Han et al., 2019; Liu et al., 2020). For instance, research has established the particular benefit of applying strategies such as the aforementioned VOTAT strategy alone or in concert with other related strategies for successful CPS performance (Molnár and Csapó, 2018). Additionally, the time students spend on individual complex problems has been shown to influence their probability of solving the problem successfully or unsuccessfully (Scherer et al., 2015). A study by Ren et al. (2019) uncovered how students can successfully balance multiple goals to be achieved simultaneously in CPS. Additional research has sought to identify different levels of CPS proficiency in students, for example based on how they approach a CPS assessment test (Greiff et al., 2015; Stadler et al., 2020). Eichmann et al. (2020) used PISA computer-based process data to uncover differences in students' CPS performance based on their sex and ethnic background: the higher CPS success rates found among boys compared to girls were attributable to differences in exploration behavior between the sexes, whereas the behavioral differences investigated were unable to account for the performance differences between students with versus without migration backgrounds.

In summary, as demonstrated by the selected research endeavors described above, computer-based process data analysis has greatly supported the investigation of students' competence levels in crucial skills such as CPS (for an overview of computer-based process data use in CPS, see also Herde et al., 2016). At the same time, computer-based process data analysis has helped to uncover opportunities to improve students' skills in these areas by means of training programs in digital learning environments (e.g., Azevedo, 2007). Moreover, as computers and digital learning and assessment tools become increasingly prevalent in the educational context, we can expect further advancements based on computer-based process data analysis in the near future. Consequently, we will now discuss potential challenges and future focus areas for computer-based process data analysis, after providing a broad summary of its current state of application in the educational measurement domain.

Summary, challenges, and future directions of computer-based process data analysis in educational measurement

We have seen that computer-based process data analysis in educational measurement carries a variety of benefits and challenges simultaneously for both educational stakeholders and researchers. Despite the fact that this promising research tool emerged not long ago, it has already produced several noteworthy advancements, as described throughout this article. Computer-based process data analysis has evolved into a versatile method for evaluating students' learning progress in order to create specifically targeted assessment and training programs for educationally relevant competencies. As such, computer-based process data analysis represents an important means of drawing inferences about students' performance in both formative and summative assessment contexts (Greiff, 2020). On the other hand, the increasingly fine-grained, rich nature of computer-based process data necessitates the development and continuous refinement of psychometric models that are able to extract meaningful information from increasingly complex raw log files. Today, computer-based process data analysis has become an established and crucial tool for improving educational measurement across the globe. Moreover, as technology continues to advance, we can expect that use of computer-based process data analysis in and beyond the educational context will expand rather than contract in upcoming years (Bergner and von Davier, 2019; Dosta et al., 2020).

Turning to potential future directions for computer-based process data analysis in educational measurement, three aspects must be considered: (a) the ongoing changing nature of assessment; (b) the evolution of digital learning environments; and (c) the increasing richness and diversity of computer-based process data, which calls for powerful and flexible statistical analysis tools. The opportunities and challenges associated with each of these aspects will be considered individually below, in order to provide some suggestions about where the use of computer-based process data analysis for educational purposes may be headed in the near future.

Firstly, we have already discussed the increasing use of computer-based process data analysis in both formative and summative assessment contexts. Both approaches represent particularly relevant educational measurement practices, and, today, they are frequently used in conjunction (Owen et al., 2014; Yang and Li, 2018). In addition, diagnostic and portfolio assessment are also becoming increasingly relevant (Chen et al., 2007; Saeed et al., 2018). Diagnostic assessment is strongly related to formative

assessment, and primarily seeks to unravel how well students are prepared for the specific difficulties they experience when working on a particular task (Csapó and Molnár, 2019). In portfolio assessment, students hand in different assignments to their teacher and are then given the possibility to revise these assignments based on their teacher's feedback. After these revisions have been made, each assignment is then handed in again and added to the student's portfolio, which serves as the primary method of assessing their overall learning progress over the course of a full semester or school year. As such, portfolio assessment features elements of both formative and summative assessment (Steen-Utheim and Hopfenbeck, 2019). Thus, as educational practice moves away from exclusive reliance on summative assessment, additional assessment approaches have emerged in recent years and are likely to continue to emerge and be refined in the future. These developments will involve the collection of a multitude of computer-based process data, and new types of computer-based process data will become available to both educational stakeholders and researchers (Shute et al., 2016a).

Secondly, throughout this article, we have presented several digital learning environments that have been developed to guide students through the acquisition and/or refinement of a specific skill. Over the last decade, these digital learning environments have largely evolved into digital game-based learning environments (Loh, 2012). The game-based nature of these environments is beneficial due to students' high levels of satisfaction when working with such programs, thereby keeping students interested, keen to learn, and entertained at the same time (Sawyer et al., 2018). Such digital game-based learning environments inherently produce a considerable amount of computer-based process data. For instance, in a meta-analysis of game-based learning, Qian and Clark (2016) discovered that asking students to work with digital game-based learning environments led to improved levels of critical thinking, creativity, communication, and collaboration. We can therefore see these types of digital learning environments being used increasingly often in educational contexts in upcoming years.

All in all, as with the observed changes in assessment approaches described above, the fact that digital learning environments are continuously evolving will impose new challenges but also new opportunities for computer-based process data analysis in educational measurement. These noteworthy developments in assessment type and methodology will lead to the availability of an increased amount of even more fine-grained computer-based process data in the future. This brings us to the final, and most crucial, aspect to be considered: the trade-off between the richness of computer-based process data and the power and suitability of statistical tools to analyze these data in a meaningful way. Indeed, as a result of the increasingly complex and comprehensive assessment approaches employed in educational contexts, the log files representing the basis for computer-based process data analysis are becoming increasingly fine-grained and difficult to scrutinize (Kumar and Chadha, 2011). Moreover, how to address the potential issue of missing and/or inaccurate data has been discussed in multiple studies, highlighting the importance of quality assurance in computer-based process data analysis (Weeks et al., 2016; Yamamoto and Lennon, 2018). Furthermore, in addition to computer-based process data generated by students completing tasks on laptops and tablets, which can at this point be seen as rather "traditional," other avenues providing complementary computer-based process data are likely to evolve in the future. For instance, technology-based process data from eye tracking (Bergner and von Davier, 2019; Emerson et al., 2020) and physiological sources such as blood pressure, heart rate, and electrodermal activity may be collected as a student works on a digital learning environment task (Sharma et al., 2020; Vrzakova et al., 2020). Moreover, computer-based process data from outside school, including students' interactions with smartphone learning apps they engage with in their leisure time, present an additional source of information relevant for their educational progress (Markowitz et al., 2014; Sin and Muthu, 2015). In other words, the current and potential future sources of computer-based process data for educational purposes seem almost unlimited. Consequently, it will become paramount for educational stakeholders to prioritize the analysis of certain kinds of computer-based process data over others due to the increasing variety of available information. In turn, the creation and refinement of statistical tools for successful, valid, and interpretable computer-based process data analysis will be necessary. As discussed in this article, several such tools already exist today, and we are confident that their development and refinement will continue in the future.

Overall, in its current form, computer-based process data analysis represents a valuable tool for both educational stakeholders and researchers to evaluate and advance educational measurement policies and practices. Since its inception in the final stages of the 20th century, computer-based process data analysis has become a standard method for investigating students' learning progress and learning success. Given the promising possibilities of this evolving technology, we expect computer-based process data analysis to become increasingly present in the future in the everyday lives of educational decision-makers, teachers, and researchers, who share the common goal of providing today's students with a state-of-the-art education in order to support and prepare them for the challenges they will face throughout and after their educational journey.

Introduction

A network is defined as a set of ties or connections among a group of nodes or entities. In education, relational data or data with network structure can arise from a variety of situations. For example, the friendship relationships among a group of students can be represented by a network where the nodes are the students and the ties are the friendships among them. The nodes need not be students, they could be teachers, schools, or even actions on an assessment. Similarly, the ties or relationships could range from collaboration to romantic interest to even temporal sequences.

Data structure often informs the methods or models that should be used for analysis. For example, student observations nested within teachers or schools often require multilevel models to accommodate the hierarchical sampling design of selecting schools and then students for data collection. Similarly, repeated measures data generally require models that account for temporal dependence. Alternative models are required because model assumptions, such as independent and identical distribution of observations, of other models are not met.

Network data have quite complicated and often ill-defined dependence assumptions. Consider a simple network of children in an elementary classroom where the tie is defined as playing together at recess. Whether two children play together at recess is not necessarily independent from whether two other children play at recess. Consider three children—A, B, and C—where A and B play together. Whether A and C play together is dependent on whether A and B play together and whether B and C play together. In fact, whether A and C play also depends on how many other children are playing with A and how many other children are playing with C and if any of their mutual friends are playing together. As a result, general/generalized linear models that assume independent observations are not appropriate for these data.

Due to the complex interdependency among network ties, specialized models for network data are recommended. The purpose of this paper is to discuss some of the models that have been and could be used in education research. In the next section, we present network notation and terminology and briefly discuss exploratory analysis. Our presentation of network models is divided across the following sections, and we conclude with a discussion of future work.

Network notation and terminology

Consider a peer network of students in fifth grade in an elementary school. The network consists of the students, and the tie is defined to be friendship. The way in which this information is collected is often through a survey in which students nominate or list their friends. Other methods for network data collection include observations in which a third party observes which students interact or in which students list the relationships among all other students, including themselves.

Regardless of the data collection method, the resultant data generally include an ordered pair of students and whether they are friends for all possible pairs of students. One way to organize this information is through an adjacency matrix, an $n \times n$ matrix A such that A_{ij} represents the presence of friendship from node i to node j . Thus $A_{12} = 1$ indicates that node 1 nominated node 2 as a friend whereas $A_{34} = 0$ suggests that node 3 did not consider node 4 a friend.

Depending on the type of network tie, adjacency matrices may be symmetric or asymmetric. The relationship, being on the same soccer team, results in a symmetric adjacency matrix whereas something like romantic interest or even friendship could result in asymmetric matrices. The corresponding ties are considered undirected (soccer team) or directed (romantic interest). Furthermore, the values of the entries of A may also represent the nature of the relationships. A friendship adjacency matrix with binary entries

Fig. 1 The sociogram or network plot shows the ties (arrows) among a set of nodes (vertices).

represent the presence or absence of friendship whereas a continuous matrix could represent the strength of the relationship or frequency of interaction. For simplicity, the statistics and models that appear throughout this article assume binary asymmetric networks.

Network data are commonly visualized with a sociogram or network plot with nodes as vertices and ties indicated either by edges (symmetric ties) or arrows (asymmetric ties). As an example, consider the 8-node network given in [Fig. 1](#). The corresponding adjacency matrix is given as

$$A = \begin{pmatrix} \text{NA} & 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & \text{NA} & 0 & 0 & 0 & 0 & 0 & 0 \\ 1 & 0 & \text{NA} & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & \text{NA} & 1 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 & \text{NA} & 0 & 1 & 0 \\ 0 & 0 & 1 & 0 & 0 & \text{NA} & 0 & 0 \\ 1 & 0 & 0 & 1 & 0 & 0 & \text{NA} & 0 \\ 1 & 0 & 1 & 0 & 0 & 1 & 1 & \text{NA} \end{pmatrix}$$

where $A_{ij} = 1$ indicates a tie from i to j . Note that we write NA (or zero) along the diagonal to signal that nodes do not have ties to themselves.

Consider [Fig. 1](#) as one of many possible networks we might observe among these eight children. There are certain statistics used to characterize and summarize networks, which are calculated directly from the adjacency matrix. We review the most common statistics but recommend texts such as [Wasserman and Faust \(1994\)](#) or [Carolan \(2013\)](#) for a comprehensive list of descriptive statistics.

Let us assume the network in [Fig. 1](#) is a network of fifth grade friendships; there are 8 nodes in this network. Density is the proportion of observed ties given all possible ties defined as $\frac{\sum_{i,j} A_{ij}}{n(n-1)}$ where n is the number of nodes. Note that we do not allow nodes to have ties to themselves so that total number of all possible ties among n nodes is $n(n-1)$. The density of this network is $\frac{15}{56} = 0.27$.

Another statistic is reciprocity, the extent to which directed ties are reciprocated. For every tie from a to b , what proportion of those ties also has a tie from b to a ? Reciprocity can be calculated as the count of the number of bidirectional ties divided by the total number of observed ties; in our example network the reciprocity is 0.5. Transitivity is similar except that it enumerates the number of transitive ties instead of bidirectional ties. A transitive tie is a tie in either direction between a and c given ties in either direction among a and b and b and c .¹ The transitivity of our network is approximately 0.57.

¹There are additional formulas for reciprocity and transitivity. See [Wasserman and Faust \(1994\)](#).

Other common network statistics are at the node or edge level and focus on centrality. Degree is one measure of node centrality and is defined as the number of ties coming in and out of a specified node. For directed ties, in-degree is the number of ties pointing toward a node and out-degree is the number of ties pointing out from a node. In- and out-degrees for a node x are calculated as $\sum_i A_{ix}$ and $\sum_j A_{xj}$ respectively. In [Fig. 1](#), node 8 has an in-degree of 0 and an out-degree of 4 whereas node 5 has an in-degree of 2 and out-degree of 2. Many network statistics can be calculated easily using the `igraph` package ([Csardi and Nepusz, 2006](#)) which is available for R and Python.

Network statistics help researchers systematically characterize the networks of interest. A network that is highly reciprocal might indicate something either about the type of network tie, the individuals in the network, or some external effect on the network. Similarly, differences in density or transitivity or distributions of node degree help researchers better understand their networks and may inspire research questions about the networks they have observed.

Although network statistics are an important part of network analysis, they do not necessarily address why or how a network has certain features. Social scientists are often interested in why network ties form or dissolve and how these network ties impact individual outcomes such as behavior or opinions. In the next two sections, we present two types of social network models: social selection models and social influence models. Social selection models can help researchers quantify how networks form whereas social influence models quantify the relation between an existing network and node outcomes.

Social selection models

Consider our network of fifth grade students in a classroom. The network summaries (graphical and numerical) may reveal that nodes with similar attributes are more likely to be friends or that certain types of students are more likely to be nominated. A social selection model can formalize these patterns and quantify the extent to which node-level attributes predict network ties. That is, social selection models allow us to estimate the association of certain attributes such as gender and race with friendship.

To appropriately accommodate the inter-dependence among network ties, broadly two classes of social selection models have emerged in the literature: exponential random graph models (ERGMs; [Anderson et al., 1999](#)) and conditionally independent dyad (CID) models ([Dabbs et al., 2020](#)). Although these classes are not mutually exclusive, standard ERGMs and CID models generally differ in how they accommodate tie dependence.

ERGMs explicitly define the dependence structure by including network statistics in the model ([Frank and Strauss, 1986](#); [Anderson et al., 1999](#)), and which statistics are included aligns with the assumed dependence structure among ties. The term ERGM is based on the fact that the probability distribution of a graph can be written as an exponential family; the network statistics are the sufficient statistics for the distribution ([Goldenberg et al., 2009](#); [Holland and Leinhardt, 1981](#); [Robins et al., 2007](#)). Common examples of network statistics are reciprocity, density and transitivity, although more complicated network statistics are recommended for model estimation ([Snijders et al., 2006](#)).

Alternatively, CID models incorporate latent variables to account for tie dependence; ties are modeled as independent conditional on latent variables that explain the network structure. Common examples of the CID models include the latent space model ([Hoff et al., 2002](#)), the stochastic block model ([Holland et al., 1983](#)) and the mixed membership stochastic block model ([Airoldi et al., 2008](#)). Note that some of the earliest network models, such as the p_1 model ([Holland and Leinhardt, 1981](#)) and the p_2 model ([van Duijn et al., 2004](#)), could be classified as simple versions of either ERGMs or CID models. The p_1 and p_2 models account for dyad-level dependencies using sender effects, receiver effects, and reciprocity terms.

While ERGMs allow users to estimate the effects of network structures in their models, complex model specification can result in computational complications and convergence issues, thus making them slightly less desirable in real world applications ([Handcock et al., 2003](#)). While CID models do not have these estimation issues, many of these models have either some type of identifiability issue or label switching issue. Further, some researchers may be interested in precise estimations of latent variables, which requires some additional modeling constraints for comparable latent variable estimates ([Sweet and Adhikari, 2020](#); [Sweet and Zheng, 2017](#)).

Many R packages are available to fit social selection network models. For example, to fit ERGMs, there is an R package `ergm` ([Handcock et al., 2021](#)), which is part of a suite of packages in the `statnet` R package. Parameters are generally estimated using Markov chain Monte Carlo (MCMC; [Gelman et al., 2013](#)) although maximum likelihood estimation algorithms are also used, and alternatively pseudo-maximum likelihood estimation can be specified by the user. Within the `statnet` suite, there is also a package called `latentnet` ([Krivitsky and Handcock, 2020](#)) for fitting latent space models for some types of network data using MCMC. Additional specifications of latent space models for multiplex and bipartite networks can be fit using the `lvm4net` package ([Gollini, 2019](#)), which relies on variational inference for parameter estimation. Further, there are many R packages available for additional types of CID models and specific types of network data. For example, the `hlsm` ([Adhikari et al., 2014](#)) package is available for multi-level latent space models, the `NetMix` ([Olivella et al., 2021](#)) for mixed membership stochastic blockmodels, and `blockmodels` ([Leger et al., 2020](#)) for stochastic blockmodels.

Despite the number of available R packages, some network models are not accommodated in an existing R package. Users may choose to write their own MCMC algorithm to meet their needs. However, MCMC sampling software such as [Stan Development Team \(2016\)](#) and JAGS Plummer (2009) allows users without extensive coding experience to specify and quickly estimate a unique model.

An example

Although ERGMs and CID models are philosophically different, they are often used in similar ways in education research, namely to estimate the effect of node- and edge-level attributes on predicting network ties. The interpretation of the parameter estimates for these attributes is also similar. Therefore, we present only one type of model as an example.

A latent space model is a CID model where the latent variables are latent positions for each node in a low-dimensional latent social space. The probability of a tie is a function of the distance from one node to another node in the latent space. Pairs of nodes that are relatively far from each other are less likely to have a tie than nodes that are relatively close to each other.

Conditional on the latent space positions, network ties are independent of one another. Thus, one assumption is that the latent space explains network structure. For example, three nodes with mutual ties are expected to all be close to one another in the latent space, and a node without any ties to other nodes has a latent position far in the latent space.

A latent space model is given as

$$\begin{aligned} \text{logit}[P(A_{ij} = 1)] &= X_{ij}\beta - d(Z_i, Z_j) \\ Z_i &\sim \text{Normal}(0, \Sigma) \end{aligned} \quad (1)$$

where the metric $d(Z_i, Z_j)$ can be any distance metric such as Euclidean distance. A standard prior for Z_i is a d -dimensional vector from a normal distribution with mean 0, and Σ is a diagonal variance-covariance matrix. Thus, the probability of a tie from i to j is a function of covariates X and their parameters β as well as the distance between Z_i and Z_j in the latent space. In the presence of covariates, the latent space positions represent residual network structure not explained by the covariates.

Social science researchers are generally most interested in the regression coefficients for covariates $X=(X_1, X_2, \dots, X_p)$, which are typically attributes about the nodes or the edges among them. In a directed network, a covariate could be information about tie sender (nominator) or the tie receiver (nominated); otherwise a node-covariate is used for an undirected network. Examples of node-level covariates include age, gender, and race. An edge-covariate relates to the pair of nodes or dyad itself. Analogous examples include difference in age, being the same gender or race.

Consider the following toy example in Fig. 3 of an undirected friendship network of 15 fifth grade students for whom we have their choice of favorite recess activity. These categories are arbitrary so let us assume that nodes 1–4 enjoy sports, 5–8 enjoy playground equipment, 9–10 enjoy art, and 11–15 enjoy pretend play. The nodes in the network plot are colored based on these categories.

The ties in Fig. 2 are undirected so we do not have sender and receiver specific variables, but we can include node-level covariates and edge-level covariates when modeling undirected networks. For example, suppose X_{1ij} is indicator for whether the node i 's favorite recess activity is sports. Then we are interested in whether students who love sports are more or less likely to have friends. An edge-level covariate might instead focus on whether i and j enjoy the same favorite activity; that is, $X_{2ij} = 1$ indicates i and j have the same favorite recess activity. Other edge-level variables could be difference in age or having a tie at a previous time.

If the ties in Fig. 2 were directed, we could have sender and receiver specific covariates; X_{1ij} might indicate that the sender's favorite activity is sports, and we might be interested in whether sports players are more likely to nominate others as friends than other types of students. Alternatively, X_{1ij} could indicate that the receiver's favorite activity is sports so we are now interested if sports players are more popular (more likely to be nominated as a friend).

For our example, Fig. 2 suggests that students with the same favorite recess activity are more likely to be friends because nodes of the same color tend to share ties, and nodes of different colors do not share many ties. We could then fit the LSM given in Eq. (1) where X is a single covariate, such that $X_{ij} = 1$ if students i and j selected the same favorite recess activity.

Fig. 2 Example of a 15-node friendship network based on favorite recess activity; Nodes 1–4 enjoy sports, 5–8 enjoy playground, 9–10 enjoy art, and 11–15 enjoy pretend play.

of fifth grade networks within each school as distinct and independent. Similar to how multilevel regression models model the variability both within and between schools, multilevel network models account for variability in tie probability within and between networks.

Multilevel social selection models have been used to examine the associations of teacher attributes on advice-seeking network ties. Research has found positive effects of being a teacher leader (Spillane et al., 2012) and being within relatively close proximity to each other (Spillane et al., 2017) on advice-seeking ties. There were negative effects of teaching English Language Learner students (Hopkins et al., 2015) and being of a racial minority (Bristol and Shirrell, 2019) on advice-seeking ties. These models have also been used to explore relationships among students; Frank et al. (2013) explored the associations with several covariates and found being in the same class predicted new friendships among adolescents.

There are multilevel extensions for both ERGMs and CID models although multilevel CID models have been used more often in the education literature. For that reason and for brevity, we will limit our discussion to those models. Snijders and Kenny (1999) first introduced a multilevel social selection model for family relationship data where the network was defined by the family; this model included sender, receiver, and dyad random effects. Zijlstra et al. (2006) introduced a similar model, the multilevel p_2 model, and Sweet et al. (2013) introduced a multilevel extension to the latent space model.

A multilevel network model assumes networks are independent and isolated; that is ties across networks do not exist. A multilevel latent space model is given as

$$\begin{aligned} \text{logit}[P(A_{ijk} = 1)] &= X_{ijk}\beta_k - d(Z_{ik}, Z_{jk}) \\ Z_{ik} &\sim \text{Normal}(0, \Sigma) \end{aligned} \quad (2)$$

where A_{ijk} now denotes the presence of a tie from node i to node j in network k . As in other random effects models, regression coefficients β_k may vary across the networks. Note that the latent space positions are different for each network, and the distribution for each network's latent position could also vary. Finally, X_{ijk} may represent a sender-, receiver-, edge- or network-level covariate.

Multilevel social selection models both accommodate the nested data structure common in education, and also allow researchers to explore differences among networks. For example, the effect of choosing the same favorite recess activity may vary across schools, and understanding the extent to which this effect varies might be of interest. In addition, the models also accommodate network-level variables, so examining which school-level variables explain some of the variability observed across networks is also relevant. Furthermore, network-level variables include covariates such as a experimental condition, and these models can be used to estimate treatment effects in cluster randomized trials (Sweet et al., 2013).

Longitudinal extensions to social selection models

Longitudinal data is an example of a nested data structure in which repeated observations are collected over time for each unit. Network data can also have a longitudinal structure. For example, a friendship network of students at a school can be collected over multiple years, and these network ties are correlated over time. If two students were friends in the past they are also likely to be friends in the future. Thus, these correlations in longitudinal network data need to be accounted for in social selection models. The longitudinal network models account for such correlation over time and are similar in structure to the multilevel network models.

Both ERGMs and CID models have been extended to model longitudinal network data. Using models called temporal ERGMs, Hanneke et al. (2010) have studied the networks observed over discrete time points. Temporal ERGMs generally condition on the network at time $t - 1$ to model the network at time t , but similar to the ERGMs for cross-sectional network data temporal ERGMs also use network statistics in the model to define the within-network tie dependence. Examples of network statistics can include statistics representing stability, density, and overall reciprocity, observed in the networks at time t and $t - 1$. Other examples of longitudinal ERGMs include Robins and Pattison (2001) and Almqvist and Butts (2013).

CID models have modeled networks observed over multiple time points by introducing longitudinal dependence on the latent variables (e.g., Sewell and Chen (2015), Westveld and Hoff (2011), Xing et al. (2010)). Longitudinal CID models also condition on the network at time $t - 1$ to model the network at time t . And analogous to cross-sectional CID models, the network ties at each time point are assumed to be independent given the latent variables at that time point and in the previous time points.

For simplicity and consistency, we present the longitudinal version of the LSM. Sarkar and Moore (2005) introduced a predictive latent space model for temporal networks, and Sewell and Chen (2015) have similar work extending the latent space model to account for longitudinal networks. A longitudinal latent space model for networks $A_1, \dots, A_T$ observed over T time points, can be written as

$$\begin{aligned} \text{logit}[P(A_{ijt} = 1)] &= X_{ijt}\beta_t - d(Z_{it}, Z_{jt}) \\ Z_{it} &\sim \text{Normal}(Z_{i(t-1)}, \Sigma), \text{ for } t = 2, \dots, T \\ Z_{i1} &\sim \text{Normal}(0, \Sigma) \end{aligned} \quad (3)$$

where A_{ijt} now denotes the presence of a tie from node i to node j at time t . The longitudinal correlation in the networks is accounted for by a random walk plus noise dependence in the latent positions Z_{it} over time. We could further extend this modeling framework to introduce dependence on the coefficients ($\beta_1, \dots, \beta_T$) for each covariate, analogous to time-varying growth models. The idea behind longitudinal LSMs is that nodes that are close in latent positions in previous time points are more likely to also be close in future, and thus, nodes that have ties in the previous time points have higher likelihood to have ties also in the future.

We also note that longitudinal network data has an additional complication in that the nodes in the network may change over time. Immigration of individuals into a network and emigration out of a network is common in educational data. For example, networks of students are likely to vary over years as students move or graduate; similarly, teacher turnover is quite common in schools between teachers leaving the profession, transferring to new schools, and new teachers graduating. Some longitudinal social selection models accommodate node immigration and emigration (Adhikari et al., 2021).

Social influence models

Social influence refers to the phenomenon where an individual's behaviors, opinions, or beliefs change as a result of their network ties, often becoming more similar to those with whom they are connected. Social influence in education is quite common, from students learning dances from each other (Marshall, 2019) and adolescents spending money on items that their peers would see (Bachmann et al., 1993) to more rebellious behaviors such as smoking or drug use (Ennett et al., 2008). Students are not the only individuals susceptible to influence; teachers and other staff members can be professionally influenced by one another (Supovitz et al., 2010), and school leaders may be influenced by the policies and practices implemented in other schools (Muncey and McQuillan, 1996).

Thus, social influence models aim to estimate the effect of these network ties on some outcome of interest, these models incorporate network ties as explanatory variables rather than outcomes. In our context of fifth grade students, we might be interested in whether interest in coding is influenced by friendship ties. We then hypothesize that students will become more interested in coding if they are friends with someone with a strong interest in coding; likewise, students with friends who are very uninterested in coding may be less inclined to participate in coding.

In the social network literature, there are a variety of models for social influence. One prominent model is called the network autocorrelation model (Doreian, 1989; Leenders, 2002), which is similar to the autologistic actor attribute model (ALAAM; Darganova and Robins, 2013; Robins et al., 2001). The autocorrelation results from the outcome of interest being modeled as a function of that outcome and the network. Consequently, autocorrelation models make the assumption that the network has reached a state of equilibrium, which is a strong assumption and may not hold in many educational situations.

A temporal version of these models relaxes this assumption, and these versions are called exposure models (Valente, 2005), temporal versions of network autocorrelation models (Leenders, 2002) or social influence models. These models use a temporal relationship such that an outcome variable Y at time t is predicted by the network ties and the nodes' values of Y at time $t - 1$. This model is given as;

$$Y^t = \alpha WY^{t-1} + X\beta + \varepsilon; \quad (4)$$

where the continuous outcome Y is measured at two time points, W is a function of the network, X is a set of additional covariates, α is the estimate of network influence, and ε is random noise. In many applications W is a weight based on the network ties. For example, if nodes are influenced by those with whom they are connected, then W_i could be defined as a vector indicating with which nodes i is connected and then scaled by the number of ties i has, $W_{ij} = \frac{A_{ij}}{A_i}$. Note that in directed networks, W could be defined in terms of in-ties or out-ties. Other specifications of W certainly exist; Sweet and Adhikari (2020) proposed an influence model in which node influence is based on their relative latent space position.

Consider the following example of the toy network given in Fig. 4 (top left) in which the nodes are colored based on their interest in coding. The colors shown, going from light yellow to peach to red to magenta indicate the interval from no interest to strong interest at time 1. The other plots in Fig. 4 illustrate how interest in coding may change based on our assumption about social influence. If we assume nodes are only influenced by those nodes they nominate (out ties), then Fig. 4 (top right) shows the resulting node attributes at time 2. Under this assumption, nodes 1 and 8 become less interested in coding, for example.

Another assumption is that nodes are influenced by all of their ties, regardless of direction, and Fig. 4 (bottom left) shows that node 1 is now influenced by both node 3 and node 8, and their interest in coding no longer decreases. Finally, in the plot given in Fig. 4 (bottom right), we assume nodes are influenced by all of their ties but also by themselves; that is, now $X = Y^{t-1}$ in Eq. (4) as opposed to $X = 0$ in the other examples. Under this assumption, node 8 has the smallest decrease in coding interest compared to our other assumptions.

Which mechanism of social influence one employs in the model depends on the context, including both the type of tie and the outcome of interest. Including a time 1 node attribute in the model is standard, but selecting whether nodes are influenced by in-ties, out-ties, or both depends on the context. Nodes are likely most influenced by the nodes they nominate (out-ties) in relationships such as advice-seeking or admiration whereas relationships such as friendship or information-sharing tend to be more reciprocal in terms of influence.

In the education research literature, there have been several studies investigating social influence among students. For example, Broda et al. (2018) fit social influence models similar to Eq. (4) to estimate the impact of networks on supportive practices for student college admission; DiGuseppi et al. (2018) fit network autocorrelation models to study resistance to binge drinking; and Huang et al. (2014) found that student exposure to risk behaviors through online friendship networks was associated with their own risk behaviors.

Fig. 4 Changes in node color illustrate changes in node attributes as a result of social influence where assumptions of influence may vary. Ties may be influenced by out ties, all ties, or all ties as well as themselves.

Multilevel and longitudinal extensions of social influence models

Social influence studies in education often require a multilevel version of Eq. (4) because these studies focus on networks of students nested in classrooms/schools or networks of teachers nested in schools. A multilevel social influence model is given as

$$Y_k^t = \alpha_k W_k Y_k^{t-1} + X_k \beta_k + \varepsilon, \quad (5)$$

where k indexes the network. The outcome of interest is still measured at two time points and the ties in network k are used to determine W_k . Eq. (5) may include fixed or random regression coefficients.

Multilevel social influence models are quite prevalent among analyses of teacher network data in education. Frank et al. (2004) and Frank et al. (2014) employed multilevel social influence models to explore teacher social influence on the use of technology and instructional practices respectively. Penuel et al. (2012) studied network effects on professional development for writing instruction. There are few examples of multilevel influence models of students, but Cooc and Kim (2017) found that reading with someone with a higher reading ability score was associated with improved reading ability.

Longitudinal social influence models also exist. O'Malley et al. (2020) extended the social influence model for longitudinal networks and longitudinal outcome data. The core model is given as

$$Y_{it} = \beta_1 Y_{i(t-1)} + X_{i(t-1)} \beta_2 + \alpha W_{(t-1)} Y_{i(t-1)} + \varepsilon_{it}, \quad (6)$$

where the weight matrix W_t at time t is derived from the weights based on the network at time t so that W_t also changes over time. Note that the model assumes the influence effect α is constant over time. O'Malley et al. (2020) also assumes Eq. (6) to be a Markov transition model such that the time between observations at time $t - 1$ and t is assumed to be sufficiently small such that any change

in the outcome of node i has yet to impact those of nodes $j \neq i$. A similar model in which W_t was defined as the weight from out-ties in the network at time t was used by [Spillane et al. \(2018\)](#) to estimate the effect of longitudinal network ties on changes in beliefs about teaching mathematics.

Another version of the longitudinal influence model given in [Eq. \(6\)](#) is to include an interaction term to estimate moderation by network characteristics; [O'Malley et al. \(2020\)](#) included a term in their model to estimate how peer effects are moderated by how important/focal a node is in the network. For example, in an advice-seeking network, leadership status could moderate the influence of collaboration between teachers on their students' performance.

Modeling selection and influence

One criticism of modeling cross-sectional data is that we are often unable to disentangle social selection from social influence to make a causal inference on the network. That is, if two children are friends and they both like playing sports at recess, are they friends because they both like playing sports or do they both like playing sports because they are friends? One solution is to use longitudinal data, because it provides a temporal constraint on how ties can impact nodal attributes and vice versa ([Frank and Xu, 2020](#)). Friendship at time 1 can be used to predict changes in recess activities at time 2, and favorite recess activities at time 2 can be modeled as predictors of new friendships at time 3.

Alternatively, co-evolution models involving stochastic actor oriented models ([Snijders, 1996](#)) model the co-evolution processes of selection and influence over time ([Steglich et al., 2010](#)). These models view network evolution and influence as a co-evolving system, and the selection and influence processes are separated by modeling these two phenomena jointly with sequence of longitudinal observations. These models are fit using the software Simulation Investigation for Empirical Network Analysis (SIENA; [Snijders et al., 2008](#)), and they require longitudinal network data for at least two consecutive waves. One assumption is that ties evolve between waves as a result of nodal attributes. SIENA is a flexible software that allows for small amounts of missing data as well as emigration and immigration of nodes (e.g., students leaving the school or new students entering the school).

Research applying SIENA have mainly been used in the psychological and public health literature that involve networks of students in schools. For example, both [Wölfer and Scheithauer \(2014\)](#) and [Rambaran et al. \(2020\)](#) studied the social influence of bullies; [Osgood et al. \(2013\)](#) found selection and social influence effects of alcohol use in friendship networks; and [Rivas-Drake et al. \(2017\)](#) found selection and social influence effects of ethnic-racial identity. Co-evolution models have great potential for education research when longitudinal data is available.

Discussion

The organization of students and teachers in schools has created opportunities for networks since group learning requires some kind of interaction. Similarly, schools provide more than simply academic instruction; student interactions are also important for the development of social and emotional competencies. Therefore, understanding why certain individuals connect and how those connections impact other outcomes is important for education research. By highlighting classes of network models, our aim was to showcase models commonly used in education research. Social selection models focus on associations between nodal attributes and network ties, and social influence models focus on the effects of the network on nodal outcomes.

We have focused on networks of students or teachers because these networks are the most prevalent in education research, but network nodes need not be individuals. For example, nodes could be items on an assessment (e.g., [Jin and Jeon, 2019](#)), and we might be interested in modeling the co-occurrence of correct items. Alternatively, an item may require several steps or actions for a correct answer; one could think of the possible actions as nodes and the temporal sequence of steps from one action to the next as the network ([Zhu et al., 2016](#)). Measurement models for network data are an emerging area, and we look forward to future developments. A related field is that of network psychometrics ([Epskamp et al., 2017](#); [Marsman et al., 2018](#)), in which the relations among these items or the constructs represented by these items are modeled using a graphical modeling approach. These models are fairly different from the network models described in this manuscript. Rather than using an observed network as a predictor or outcome for inference; the goal is rather to infer the network, defined as the connections among the nodes/constructs.

Furthermore, we have focused on network models common in education research, but this article is not a comprehensive survey of network models more generally. Methodological research on networks exists throughout a variety of disciplines, including research with applications in computer science, statistics, medicine, and public health. Some recent methodological work includes methods for missing data ([Krause et al., 2020](#)) and measurement error ([Lee, 2019](#)) along with new models for co-evolution ([Minhas et al., 2016](#)) and mediation ([Liu et al., 2021](#); [Sweet, 2019](#)). Social networks have even appeared in the causal inference literature ([Lee and Ogburn, 2020](#)).

With respect to education research, there are several areas of future research in network modeling that should be particularly impactful. Future work on missing data will be useful for modeling teacher networks which tend to gain/lose a large percentage of its nodes over time, making longitudinal modeling difficult. Similarly, additional research on mediation models for social networks will help researchers employ these models to analyze experimental intervention data. Finally, there is an area of research

around spillover effects or network interference, that is, the idea that someone in a different experimental condition could be impacted due to their relationships with individuals in another condition. Network models have potential to be useful in this area of research as well.

The *Standards for Educational and Psychological Testing* (AERA, APA, and NCME, 2014) combine certification and licensure under the heading of *credentialing* examinations. They are certainly similar in some ways, but they are not one and the same (Clauser et al., 2006). According to the United State Bureau of Labor Statistics (USBLs), forty-seven percent of all civilian workers require some type of credential, with 6% requiring a specific certification and almost 20% holding a professional license. Professionals in health care and technical occupations account for almost 95% of all required credentials (USBL, 2021).

Certifying organizations tend to be non-governmental agencies that grow out of professional societies or professional interest groups. Most certifications result in titles or low-to-moderate-stakes credentials issued as part of a voluntary process. That is, the certification candidates choose to undergo the evaluative process to acquire a particular badge, title or credential. Each certificate provides official verification that an individual has met a specified set of standards of demonstrated knowledge, skills or/other professional competencies. The credentialing process can range from some informal verification that the candidate completed specialized or continuing education to more formal and extensive evaluation process that includes meeting eligibility qualifications and undergoing one or more competency assessments. Certifications vary insofar as what is being credentialled—from entry-level of knowledge or proficiency skills to highly specialized and in-depth demonstrations of excellence.

Licensure is a regulatory process implemented via legislation or executive order to protect the public against potential harm or injury from unsafe or otherwise inappropriate professional practices. In addition to meeting specific eligibility requirements including academic credentials or degrees, amount-of-experience, or other training qualifications, licensure applicants typically have to demonstrate that they have attained a specified degree of competency to practice—often in an independent unsupervised manner. For example, in the United States, most health care professionals—physicians, nurses, physician assistants, and other allied health professionals—are licensed by state jurisdictional authorities such as state medical boards. State medical practices acts empower those state boards to enforce the law. In some cases, certification may be required as part of a licensure process. For example, teaching licenses in the US are typically regulated by an agency within the state department of education and a national certification test may be used to verify pedagogical and grade-appropriate content knowledge. Candidates applying for a law license must usually pass a comprehensive state bar examination and be admitted to the state legal bar in order to hold a license to practice law in the state or territory. Other types of licenses can cross local, state or territorial lines and either be regulated by a federal licensing authority or by reciprocal state licensing agreements. In some cases, a national licensing authority acts on behalf of its constituent state licensing boards for purposes of testing and establishing licensing eligibility. Examples include the National Association of State Boards of Accountancy and the Federation of State Medical Boards.

Recognition of credentialing as specialized area of assessment is relatively recent (Shimberg, 1981, 1982; Clauser et al., 2006; Raymond and Luecht, 2012; AERA, APA, and NCME, 2014; Buckendahl, 2017). In most ways, credentialing examinations are built on the same principles and standards of other educational, psychological and employment assessments. However, there are also some issues that remain unique and challenging for credentialing assessments. This chapter highlights seven issues relevant to designing and implementing an effective credentialing examination program: (1) carrying out a practice analysis to understand what to assess; (2) selecting or designing items and tasks to assess sometimes complex knowledge and skills; (3) designing and implementing an operational testing system for examination processing; (4) developing and maintaining a score scale; (5) engaging in standard setting activities to determine the credentialing cut scores; (6) designing and assembling efficient test forms to optimize credentialing decisions; and (7) evaluating the accuracy and validity of credentialing tests.

Practice analysis: determining what to assess

Credentialing examinations are similar in some respects to employment tests in that they should be constructed to reflect the tangible *knowledge, skills* (cognitive or physical), *abilities* or psychological traits, and professional *judgments* (critical decision-

Fig. 1 Determining credentialing test specifications.

making) for entry into a profession, to be licensed, or to otherwise maintain or renew a credential (Note that the acronym “KSAJs” is used in this chapter to reflect the constellation of attributes that could be considered in designing a credentialing test). However, unlike many employment tests, credentialing examinations do not merely rank order the candidates and select as qualified those with the highest scores (Clauser et al., 2006). Credentialing examinations instead undergo a process called *practice analysis* to determine the minimum level of KSAJ-related attributes required to be credentialed or licensed, independent of how many eligible candidates are ultimately successful. The challenge resides with deciding which KSAJs to assess and how to best assess them.

There is no single best way of carrying out a practice analysis (Clauser and Raymond, 2017; Raymond, 2001; Raymond and Neustel, 2006). In fact, Clauser and Raymond outlined eight different methods for carrying out a practice analysis. In general, most practice analysis methods fall into one of two classes: *candidate-focused* or *task-focused* methods. Candidate-focused methods tend to describe the domain in terms of the KSAJs demonstrated by qualified individuals who hold the credential. For example, a candidate-focused method might delineate and prioritize the functional roles that qualified candidates should possess. Task-focused methods emphasize the types of job-related activities (tasks) in which qualified individuals apply the KSAJs. Most task-focused practice-analysis methods incorporate statements that are then rated in terms of the amount of time typical qualified candidates spend performing each task and the perceived importance of the task.

Practice analyses can also differ with respect to the groups included in the process. Professional organization leaders, qualified subject-matter experts (SMEs) and individuals with psychometric (measurement) expertise are all likely to have input into the process of defining and refining the KSAJs to be included on a credentialing examination (Davis-Becker and Muckle, 2017). The purpose and value (or stakes) of the credential, the diversity of the eligible candidate population, and the feasibility of actually measuring the potential wide array of KSAJs in a professional domain all influence the decision as to what is ultimately assessed (Raymond and Luecht, 2012). For example, a credentialing test targeted for entry-level candidates may be substantially different than a test design to credential highly experienced professionals, or those renewing a credential after some designated period of time.

Ultimately, the goal of any practice analysis is to identify the critical KSAJs in a profession (Kane, 1982, 1997). As depicted in Fig. 1, those target KSAJs must further be refined to represent the *measurable* characteristics of competent professional practice that can be converted into a set of test specifications that guide item writing and test assembly.¹ For example, the test content

¹The term “test blueprint” is commonly used to represent the content and (crudely) the cognitive specifications for assembling tests. However, test specifications can and should also incorporate statistical/psychometric requirements such as the distribution of item difficulty and the amount of precision allocated along a score scale.

specifications for the United States Medical Licensing Examination (USMLE) Step 1 covers ten basic science disciplines (e.g., pathology, physiology, pharmacology, biochemistry & nutrition) as well as being cross-referenced to multiple physician competencies involving general principles of medicine, organ systems, and allied areas related to patient care (FSMB and NBME, 2022).

Designing the test items: how to assess the KSAs

Following the practice analysis phase, a credentialing organization must design and generate the test items to meet the test specifications and to assemble test forms. The item design and development process usually involves five steps: (1) selecting or designing appropriate item types; (2) developing item writing guidelines; (3) engaging item writers and test editors to craft and refine the individual items²; (4) pilot-testing the items to obtain performance statistics used in evaluating the items; and (5) engaging in psychometric analysis to “bank” the items for use on current or future test forms.

There are four rather broad classes of items used on credentialing assessments: (i) knowledge-based items; (ii) simulated performance items; (iii) authentic work samples; and (iv) personality and other non-cognitive assessment items (Luecht, 2017a). Some credentialing assessments include a combination of items from these four classes.

Knowledge-based items are very popular for credentialing examination because they can be developed with minimal item-writing training and editing. They tend to take less time than other item types to administer relatively large numbers of items covering a broad range of topics. And they can furthermore be easily and inexpensively scored.

Most knowledge-based items employ some type of stimulus question or scenario and a selected-response (SR) mechanism. Examples of SR include the ubiquitous multiple-choice question (MCQ) that can be machine-scored using a scanner (for paper-and-pencil tests) or using response pattern-matching on a computer-based test (CBT)—see Haladyna (2004) and Luecht (2017a). Other SR item types typically considered for CBTs include multiple-select items, select-and-reorder (prioritize) items; drag-and-drop items, items incorporating digital media (e.g., images or video segments) or exhibits, hot-spot items and problem-based sets that include two or more items associated with a reading passage or scenario (Luecht, 2017a, 2017b; Parshall and Harnes, 2008; Parshall and Brunner, 2017). Short-answer item formats are sometimes used but can be difficult to score given the large number of possible matches of candidate responses to the correct answer(s).

As implied above, these item types are typically used to assess candidates’ declarative knowledge of the professional content, including prevailing theories, principles, professional standards, standardized protocols, and common scenarios or applications. Oral interviews, essays and other types of constructed-response items (CRs) are sometimes used to assess content knowledge, but typically require human scoring to evaluate the quality and substance of the written content. There is, however, a growing interest in using natural language processing (NLP), text analytics, and artificial intelligence for *automated scoring* (Shermis and Burnstein, 2003; Shermis et al., 2015; Drasgow et al., 2006; Williamson et al., 2006).

Simulated performance item types ideally provide a realistic problem scenario that requires the examinee to engage in problem-solving, analysis and/or critical decision making (Luecht and Clauser, 2001). These types of items often attempt to measure the application of specific procedural or decision-making skills using realistic manipulatives such as reference materials or software application tools (e.g. spreadsheets or analytical software). The simulated environment may present a type of “mission” or task challenge that each candidate must attempt using the tools and resources provided by the simulated environment. One example are the computerized case simulations included on the United States Medical Licensing Examination (USMLE™) developed by the National Board of Medical Examiners (Dillon, Clyman, Clauser, & Margolis, 2002; Clauser et al., 2002). The candidates are presented with a simulated patient exhibiting particular symptoms. They may need to order diagnostic tests or therapies and manage the patient over an extended period of time. Another example is the Uniform Certified Public Accountants Examination jointly developed and administered by the American Institute for Certified Public Accountants and the National Association of State Boards of Accountancy. That examination includes simulated performance assessments that require hands-on use of spreadsheets, preparation of written memos, queries of the authoritative accounting literature, and analysis of financial documents (Devore, 2002; Devore et al., 2011).

Other types of simulations may require examinees to construct job-related, written correspondence, or to use a set of software tools to analyze a data set or solve a computer networking problem. Although there is a great deal of intrinsic appeal in the “face validity” of simulated performance item types (see, for example, Clauser et al., 2002; Ward et al., 2019), there can be substantial costs involved in developing and piloting the items, potential security risks if the number of tasks in the item bank is relatively small, and possibly limited domain sampling and contribution to the overall measurement precision of the scores or classification decisions given the amount of time required for candidates to complete each simulation (e.g., Williamson et al., 2006).

Authentic work samples have a relatively long history in both employment and credentialing settings. These types of assessments require an examinee to actually perform a work-related activity to demonstrate an integrated set of knowledge and skills in an applied setting. An example would be requiring a candidate to successfully operate heavy construction equipment such as a crane, excavator or some other material handler to carry out various designated tasks in different settings (see nccco.org). The ubiquitous

²Recently, researchers have recommended less focus on crafting individual items, emphasizing the need to focus on families of *isomorphic* items that all measure the same constellation of KSAs and behave in a statistically similar manner (Luecht and Burke, 2020). Interest in mass-production of items using a combination of templates and computer algorithms—called automatic item generation (AIG)—is also growing given the high costs of producing large numbers test items for professional credentialing examinations (see Gierl and Haladyna, 2012).

on-the-road driving test used to obtain a driver's licensure would also qualify as an authentic performance-based work sample. Given the potential sources of noise that can come into play with work samples (e.g., uncontrollable variations in the assessment setting or inconsistent application of scoring protocols in different contexts by the examiners), it can be difficult to create measurement conditions and scoring protocols that are sufficiently standardized to ensure a comparable experience for all examinees (Ness et al., 2004).

Non-cognitive assessment such as personality questionnaires or situational judgment tasks (SJTs) are often used to measure personality affects such as temperament or attributes like self-reflection, honesty, professional ethics and accountability. Measuring leadership characteristics is also an area of growing interest in some professional settings. Although there is certainly interest by certification or licensing agencies in assessing non-cognitive affects to develop blended definitions of competency that include knowledge, skills, attitudes and professional judgment, few if any certification or licensing agencies have actually attempted to implement non-cognitive affective measures as part of the initial certification/licensure steps, or even for re-certification or license renewal. Instead, continuing education and documentation of designated professional development activities are used.

Designing an operational testing system for processing the examinations

Operational testing is far more complicated than merely writing test items, building test forms, administering the forms to candidates and reporting scores. There are many test development and psychometric support procedures involved in any testing enterprise (Dragow et al., 2006). Fig. 2 provides a high-level overview of the behind-the-scenes functional processes for a typical credentialing examination program. The statistical and content test specifications guide item writing. New items or tasks are ideally pretested³ on operational test forms to gather performance statistics and evaluate their quality and suitability for use on future test forms. Items that survive the quality control vetting process can be statistically calibrated to an underlying *item bank scale*—discussed below—and made eligible in the *item bank* (i.e., the item and task repository). Items in the bank can include calibrated pretest items and existing operational items. The test assembly process brings together the items from the bank (the supply) and the test specifications (the demands).

Scores on the operational test forms may undergo additional statistical adjustments to ensure that, ultimately, all scores and interpretation—including the final pass-fail credentialing decision—fairly reflect performance on a common metric.

Fig. 2 Operational test development, quality control and item banking.

³Pretest items are typically not included in operational scoring. For this reason, the number of pretest items administered to any single candidate is relatively small (e.g., less than 20% of the total test length).

Scores and score scales: construction, maintenance, and interpretation

Most credentialing examinations are fundamentally *mastery tests*. That is, these types of examinations result in a discrete, pass-fail classification decision. There may indeed be an underlying score scale that is psychometrically maintained over time, but the score(s) are usually converted to a binary score scale: 0 = *fail* or 1 = *pass*. Although some may naively believe that an absolute cut score is a percent-correct score like 75%, the reality is that most credentialing examinations need to: (a) build the underlying statistical score scale; (b) engage in some reasonable standard-setting process to establish the cut score(s) for “mastery” on the test; (c) establish reasonable “data connectivity” and carry out appropriate scale linking analyses to maintain the same score scale and cut score(s) over time⁴; and (d) carry out various statistical and psychometric quality procedures to ensure that the scale properties and interpretations associated with the classification decision remain consistent across test forms.

The terms *scores* and *scoring* are often used in different ways. Item- or task-level scores are the dichotomous (binary) or polytomous (integer, partial-credit) points assigned to each item (e.g., 0 if wrong, 1 if correct). These scores are generated by scoring evaluators that include simple pattern matching algorithms, human scorers using a rubric, or automated scoring algorithms that employ artificial intelligence (AI) scoring models that attempt to replicate the scoring outcomes of human scorers.

Raw test scores are the weighted or unweighted number-correct or total-points earned on a test form obtained by summing the item scores. However, raw scores or percent-correct scores are not necessarily comparable across test forms that differ in average difficulty. For example, consider two forms of a 150-item credentialing examination, Form X and Y, each administered to equally proficient groups of examinees. Suppose Form X has an average score of 100 and Form Y has an average score of 105. The raw scores on these two forms are not comparable unless we make a statistical adjustment to one or both sets of scores to put them on a *common* scale.

Psychometricians use statistical *equating* or *linking* methods to establish comparable (exchangeable) scores from different test forms. A common score scale may be established early during the tenure of a credentialing examination program using one or more test forms. Scores on future test forms are statistically adjusted to make them comparable on that same common scale. For example, given our two 150-item test forms above, we might add five points to all Form X scores to make them statistically comparable⁵ to the Form Y scores. This would be called “*mean equating*”. Classical Test Theory (CTT) methods of establishing comparability between scores on different test forms include mean equating, linear equating, equipercentile equating and an array of non-equivalent groups equating methods (Kolen and Brennan, 2014).

Many credentialing-examination programs employ a different psychometric methodology for establishing a common metric across test forms called Item Response Theory (IRT) that offers many benefits that are simply not feasible with Classical Test Theory. There are numerous mathematical models that can be employed under the IRT umbrella to accommodate different types of items and response data. The technical details of implementing IRT are far beyond the scope of this chapter (see, for example, Hambleton, Swaminathan, & Rodgers, 1991; Lord, 1980). Suffice to say, IRT *calibrates* the statistical item difficulties (and, under some IRT models, other psychometric characteristics) of the individual items to a common metric that is referred to by the Greek letter “ θ ” (theta). The examinees’ scores are likewise represented on the same scale allowing psychometricians to view the location and density of items relative to the concentration of examinees and/or relative to key decision points like a credentialing cut score.

A key advantage of IRT is that all items in the bank are *calibrated* (statistically linked) to the common scale and can then be used to score examinees on that same θ scale regardless of which test form or collection of items they happen to take. IRT calibration further makes computer-adaptive testing (CAT) and multistage testing (MST) possible, where the difficulty of individual items, or larger modules comprised of multiple items or tasks, are algorithmically matched to the apparent proficiency of each examinee (Luecht and Sireci, 2011; Luecht, 2012, 2014).

Fig. 3 displays an IRT-calibrated item bank (at the left). Each circle or dot represents a single item with the shading denoting differential test content. The location of each item relative to the proficiency scale at the left signifies its difficulty. The test-assembly process (center oval) uses the test specifications (statistical target at the top and content requirements at the bottom) to build test forms. The calibrated item statistics associated with each test form are used to score the examinees on the common scale, θ . Differences in test form difficulty are accounted for by the IRT scoring process. As discussed below (see *Efficient Test Design and Form Assembly*), the statistical target at the top (middle) of Fig. 3 is called a *test information function* (TIF) target. Using an IRT-calibrated item bank and target TIF can help ensure that every test form constructed not only meets the sometimes-complicated content requirements but also provides optimal measurement precision to ensure highly accurate pass-fail classification decisions (van der Linden, 1998, 2005; Luecht, 2006, 2017a).

Reported scale scores are the point values or outcomes distributed to candidates and credentialing agencies. These scores may reflect one or more mathematical transformations of either the raw scores, equated raw scores, or IRT proficiency scores. For example, some credentialing programs use a simple transformation that specifies two points such as the mean score of a defined *reference group*⁶ and the cut score (e.g., 200 as the cut score and 250 as the reference group average scale on the reported scale). Those

⁴Smaller credentialing examination programs may elect to apply the established mastery standard to each test form. That amounts to “judgmental equating” and is generally less desirable than establishing the score scale and setting the cut once relative that established scale.

⁵In practice, we would have to employ random assignment of Form X and Y to examinees for this type of statistical equating to be feasible (i.e., we would be establishing *randomly equivalent groups* so that any apparent differences in the score distributions could be attributed to differences in test-form difficulty, see Kolen and Brennan, 2014).

⁶*Reference groups* are usually defined by characteristics such as only including first-time test takers undergoing specified training or a degree program from accredited professional schools or university programs. The theory is that the reference group remains fairly stable in its composition over time.

Fig. 3 Test assembly using an IRT-calibrated item bank.

two points can then be used to create a linear transformation equation to compute the reported scale scores. Finally, the mastery (pass-fail) classification scores reflect simple binary transformations of raw scores, equated raw scores, IRT proficiency scores, or reported scale scores. Values at or above an established cut score result in a “pass”, otherwise, the candidate receives a “fail” classification. The cut score is typically set as a specific value on an underlying IRT bank scale or CTT-equated raw-score scale and then transformed to the reported scale. It can be maintained over time by equating or linking future test forms to that same scale.

Determining the credentialing cut score

Passing a test can imply minimally acceptable knowledge and/or skills-based competency for an entry-level credentialing examination. It can alternatively signify a higher level of demonstrated KSAs (e.g. a credential for an advanced certification). The process of establishing a “cut score” is not arbitrary. Rather, a defensible *standard-setting* process is essentially mandated by the *Standards for Educational and Psychological Testing*:

Defining the minimum level of knowledge and skill required for licensure or certification is one of the most important and difficult tasks facing those responsible for credentialing. The validity of the interpretation of the test scores depends on whether the standard for passing makes an appropriate distinction between adequate and inadequate performance. Often, panels of experts are used to specify the level of performance that should be required. Standards must be high enough to ensure that the public, employers, and government agencies are well served, but not so high as to be unreasonably limiting. Verifying the appropriateness of the cut score or scores on a test used for licensure or certification is a critical element of the validation process. (AERA/APA/NCME, 2014, p. 176)

There are multiple methods for setting standards but virtually all of them start with a process for selecting the panelists from an eligible pool of policy makers, subject-matter experts, or other stake-holders. The panelists typically undergo training in a particular standard-setting method and then engage in one or more rounds of rating or classifying candidate performances. The resulting cut score is usually a weighted or unweighted average of the panelists’ individual values. A credentialing policy board or other authorized group may approve the final cut score.

Three common standard-setting methods are the modified Angoff method and associated variations (Angoff, 1971), the Bookmark method (Lewis et al., 1996), and variations on the Contrasting Groups method (Berk, 1976). Cizek and Bunch (2007) provide a very thorough discussion of the array of standard setting methods, their similarities and differences, and issues related to implementation and use.

The modified Angoff method employs probability ratings of individual test items on one or more reference test forms for a theoretical group of *just-qualified candidates* (e.g., 100 credentialing candidates who are just at the threshold in terms of their performance on the reference form[s]). The cut score is a function of the summed probabilities on the reference form(s) with the results usually averaged across standard-setting panels.

The Bookmark procedure orders the items on a prescribed test form from easiest to hardest and instructs the panelists to place the conceptual “bookmark” between items that separate qualified from unqualified candidates answering the items at a designated probability of correctly answering the items. When used in an IRT context, the bookmark for each panelist corresponds to their recommended cut score.

Finally, Contrasting Groups and related holistic methods separate individual candidates who took the test or their performance profiles into two groups, qualified and unqualified candidates, based on the panelists’ judgments about what it takes to deserve the credential. The cut score is determined as the point that optimally separates the two distributions of scores or profiles on the test. Individual panelists’ cut scores are normally averaged or otherwise aggregated to produce a single, recommended cut score. Most standard-setting events further employ two or more rounds of ratings to allow the panelists to feel comfortable with and fine tune their classification decisions (e.g., after reviewing impact data based on the selected cut score).

Once the final credentialing cut score is established and approved for use by the appropriate authority (e.g., a governing board), most credentialing organizations maintain the cut score by equating or linking new test forms to the underlying score scale. When IRT is employed, the cut score is on the item-bank scale, θ . This makes it relatively straightforward to design test forms to optimize current as well as future pass-fail classification decisions. The amount of test information targeted in the region of the cut score determines the statistical accuracy of classification decisions (see the target TIF in Fig. 3). The interplay between decision accuracy associated with cut scores and measurement precision is also discussed in more detail below.

Efficient test design and form assembly

Test-form assembly is a process of building unique or semi-unique test forms that meet designated test specifications—both statistical targets and content-related targets. For example, the test specifications may include a detailed list of relevant topics or content-related categories gleaned from the practice analysis, as well as process-oriented categories or ordered cognitive-complexity dimensions like Bloom’s taxonomy (Bloom et al., 1956). The test specifications can also include professional settings or scenarios to be covered. In contrast, the statistical test specifications reflect either the targeted average difficulty of the test and/or the desired level of precision of the scores.

An important function for IRT-based test assembly is called the *test information function* or TIF. A TIF mathematically expresses the precision of the IRT proficiency scores across the underlying metric, θ . The TIF for a given test form is comprised of item information functions (IIFs). That implies that we can select items to specifically meet a target TIF, thus ensuring that the test form provides exactly the amount of information where it is most needed—in the region of the cut score for a credentialing test (Luecht, 2006; 2017a).

Fig. 4 provides two plots that might be associated with a credentialing exam to certify minimum competence in a profession. The proficiency scale is shown on the horizontal axis. The solid-line plot represents the target TIF with the left-hand vertical scale representing the amount of information (higher is better and implies more precision). The target TIF peaks exactly at the cut score of $\theta_{cut} = -1.28$, which corresponds to the 10th percentile of a normally distributed population of candidates with average proficiency of $\mu(\theta) = 0$ and a variance of $\sigma^2(\theta) = 1$. This distribution of candidate proficiency represents a reference sample of candidates such

Fig. 4 A target TIF for a credentialing examination with a cut score at $\theta_{cut} = -1.28$.

Fig. 5 Alternative ways to display TIF functions.

as first-time test takers from a designated time frame and is indicated by the dashed line in Fig. 4—corresponding to the right-hand vertical scale. This credentialing examination would therefore pass about 90% of the eligible candidates.

The test assembly process can be performed manually by test editors or a test committee. More commonly, testing agencies are beginning to employ sophisticated mathematical optimization models that can very quickly build numerous test forms that meet all of the content and cognitive/process constraints and hit the target TIF. This latter capability is known as *automated test assembly* or ATA (van der Linden, 1998, 2005; Luecht, 1998, 2017a).

Test information can also be plotted relative to other performance-related metrics. For example, Fig. 5A shows the measurement precision as a function of normal-equivalent percentiles. Here, it is clear that the information peaks near a cut score that normatively implies a 10% failure rate. That is, this type of plot provides a normative interpretation of the test information by showing how the measurement precision of a test form is allocated relative to the target distribution of the candidates. It does not represent an absolute percentage of failing candidates. The right-hand plot shown in Fig. 5B presents the amount of test information relative to the [expected] number-correct scores on a reference test form. The horizontal axis can also be easily converted to a proportion- or percent correct-score metric.

Credentialing tests assembled without carefully designed statistical targets may exhibit score or classification inconsistencies or comparability issues across test forms. The rationale for using an unambiguous target statistical specification is three-fold. First, TIFs or other comparable psychometric targets can reflect optimal and feasible test-design specification for assembling every test form. Second, the specifications can help guide item writing/production over time to ensure that the item bank (supply) can meet those optimal measurement information demands. Third, when combined with automated test assembly, TIFs can ensure a high degree of consistency (statistical parallelism) for every test form.

Credentialing classification accuracy and validation

Test scores are rarely the sole determinant for credentialing decisions. For example, candidates may also have to meet stringent eligibility requirements that include verified training or completion of an academic degree. That said, a large part of the justification for using test scores in credentialing stems from the practice analysis and choice of test content (Clauser et al., 2006; Raymond, 2006; Clauser and Raymond, 2017). That is, as noted earlier, the test content is designed to specifically measure the knowledge, skills, abilities and judgments (KSAs) demanded of qualified [credentialed] candidates in situations typically encountered in practice.

Standard setting, in turn, provides a type of empirical validation as to the amount KSAs required for each credential. That empirical validation process justifies the choice of cut score adopted by each credentialing authority. In addition, using appropriate statistical targets for test assembly—like a target test information function (TIF) that consistently amasses most of the measurement precision for each test form in the region of that cut score—ensuring maximal classification (decision) accuracy. For example, a target TIF like the one shown in Fig. 4 provides the desired amount of precision associated with classifying candidates as “passers” or

“failers”. More information in the region of the cut score implies greater precision and fewer false positive or false negative decision errors.

Although external or predictive validation might be considered—that is, statistically correlating the credentialing examination test scores with external measures of “qualified” or “successful” candidates to empirically verify the “accuracy” of decisions,⁷ it is rarely done in practice for an important reason. Simply put, it is extremely difficult to obtain a universally acceptable criterion measure that reflects the same KSAs as the credentialing test. Rather, most credentialing examinations depend on the integrity and generalizability of the entire test design, standard setting, test-form assembly practices, and underlying psychometric processes as providing sufficient and compelling evidence for the interpretation and use of the test scores and classification decisions (Kane et al., 2017).

Conclusions

Credentialing examinations—both certification and licensure tests—present some unique challenges that distinguish them from other assessments like educational achievement tests. A primary difference is the scope and nature of the domain(s) covered. Most credentialing examinations reflect the measurable professional knowledge, skills, abilities and judgments (KSAs) required of qualified individuals in the candidate population across a wide array of typical jobs or credentialing situations. The credential normally reflects minimum competency relative to those KSAs. A practice analysis therefore serves the essential purpose of providing empirical validity evidence about the KSAs that should be included as part of the test specifications.

The choice(s) of item or task types to be included on a credentialing test (multiple-choice or other selected-response items, essays or constructed-response items, simulations, etc.) are sometimes made based on cost and other pragmatic factors. However, it seems advisable to start with the practice analysis and KSAs to determine the nature and scope of the performance evidence required to support the proficiency claims inherent in acquiring the credential. Only then should credentialing organizations select item types that will efficiently and accurately provide that evidence.

Implementing a credentialing examination program can require a fairly complex system of test development, item writing and editing, pilot testing of the test content, and psychometric analyses. The purpose of that system is to process scores and classification decisions for candidates currently taking the test. However, the system should also address future item production given test development demands, item banking, and maintenance of the score scale and cut score over time. Item response theory (IRT) was noted as a solid choice to support these system-level requirements.

Standard setting is an integral part of any credentialing examination program. Simplistically, it establishes the cut score for pass-fail classification decisions. More comprehensively, standard setting provides a formal way for mapping reasoned interpretation of the level of the KSAs expected of qualified candidates to the score scale. Once the cut score is determined—by any of various standard-setting methods—test design and assembly procedures should attempt to optimize the accuracy of pass-fail decisions (i.e., to minimize classification errors). A method of using target IRT test information functions was suggested along with automated test assembly, especially if substantial numbers of test forms are required for operational use.

Glossary

Correlation coefficient (multiple) A measure of association, ranging from 0 to 1, between a set of (at least two) variables and a single variable. For example, a multiple correlation coefficient could be used to assess the degree to which test scores and high school grades, considered jointly, are associated with college grade-point average

Correlation coefficient (simple) A measure of linear association, ranging from -1 to 1, between two variables (e.g., an admissions test score and a college grade-point average)

Differential item functioning (DIF) A phenomenon in which two (or more) groups of test takers (e.g., men and women) tend to perform differently on a test question despite having equal skill in the area that is being tested. One possible cause of DIF is the inclusion in the test question of material that is irrelevant to the proficiency that is intended to be assessed

Linear regression analysis A statistical technique used to assess the relationship between a set of predictors (consisting of one or more variables) and a criterion variable. In the admissions context, for example, test scores and high school grades are often used to predict college grade-point average

Predictive validity The degree to which a test or other measuring instrument can predict a criterion of interest, typically academic or job performance. In the case of admissions tests, the criterion is typically a grade-point average in a subsequent academic program

Range restriction A reduction in the range (distance between maximum and minimum values) of a variable that results from a selection process. For example, the SAT scores of students admitted to college typically have a smaller range than the SAT scores of applicants

Background

This article provides a brief historical perspective and then describes several aspects of higher education admissions testing in the US: the main tests used, the role of tests in the admissions process, and the evidence on predictive validity. (URLs for each of the tests are given at the end of the article). Following this is a short discussion of test fairness issues. Admissions testing in several other countries is then described.

The administration of tests for regulating admissions to universities most likely began in Europe during the eighteenth century (Webber, 1989: 37), although some reports give an earlier date (e.g., Office of Technology Assessment, 1992; Stewart, 1998). Most

accounts agree that admissions testing had been introduced in Germany and England by the mid-1800s. Standardized admissions testing took root in the US in 1900, when the leaders of 12 northeastern universities formed the College Entrance Examination Board. The College Board developed a common set of examinations that were administered by member institutions and then shipped back to the Board for scoring. Initially, the Board created essay tests in several subject areas; it later developed a new exam that contained mostly multiple-choice questions—the SAT. The first SAT contained questions similar to those included in the Army Alpha tests, which had been used for selecting and assigning military recruits during World War I. These Army tests, in turn, were directly descended from intelligence tests, which had made their US debut in the early 1900s. The SAT was first administered in 1926 to about 8000 candidates (Zwick, 2017b).

Higher education admissions testing in the US

Main admissions tests used in the US today

Admissions processes in the US are largely under the control of individual institutions and instructional programs. In most cases, these entities decide whether and how to use tests in making admissions decisions. The main admissions tests used in the US today are the SAT and ACT, used for college admission; the Graduate Record Examinations (GRE), used for graduate school admission; the Medical College Admission Test (MCAT); the Law School Admission Test (LSAT); and the Graduate Management Admission Test (GMAT), used for admission to business school. As described below, these tests are developed and produced by private organizations. Tests that are not discussed in this article include tests of English that are required of foreign students by some US institutions and admissions tests for certain professional schools, such as schools of dentistry and pharmacy.

A world event that had a substantial impact on test administration policies and practices for the tests described in this article was the outbreak of the coronavirus pandemic in 2020. The administration of tests in traditional testing centers was limited. Applicants could take the GRE, MCAT, LSAT, and GMAT, at home, with remote proctoring. In some cases, modified versions of these tests were used. The future of these alternative procedures, which are described on the websites of the testing programs, is not known as of this writing.

Today's SAT

The SAT testing program is owned by the College Board; the tests, which are primarily paper-based, are administered by Educational Testing Service (ETS) under a contract with College Board. (A computer-delivered version is used in some states and school districts). According to the College Board website, the SAT is “[d]eveloped with input from high school teachers, college faculty, and enrollment professionals [and] covers core content areas deemed essential for success in college—reading, writing and language, and mathematics.” (“SAT” is no longer considered to be an acronym, but the actual name of the test. Originally, it stood for Scholastic Aptitude Test, which was later changed to Scholastic Assessment Test. More recently, the test was known as the SAT I: Reasoning Test).

The SAT has undergone many changes in content in its nearly 100 years of existence; a history of some of these changes is provided by Lawrence et al. (2004). The most recent version of the test, which was introduced in 2016, includes a section on Reading, Writing, and Language, which consists entirely of multiple-choice questions, and a Mathematics section, which contains both multiple-choice items and questions to which the test-takers must supply an answer. The main scores are two section scores—one in “Evidence-Based Reading and Writing” and one in Math—and a total score. (An optional essay test was discontinued in 2021 except for its use in high school accountability programs. The SAT Subject Tests, which assessed the candidates’ knowledge in particular areas, have also been discontinued).

The ACT

In 1959, a competitor to the SAT program emerged—the American College Testing Program (Today, the company is ACT, Inc. and the test is simply the ACT. Like “SAT”, “ACT” is no longer considered an acronym). In its early years, the ACT was administered primarily in Midwestern states, but it is now considered interchangeable with the SAT by most institutions. Like the SAT, the ACT is primarily paper-based but is delivered via computer in some states and school districts.

From the beginning, the ACT was somewhat different from the SAT in terms of underlying philosophy: While the SAT consisted only of verbal and mathematical sections, the ACT was more closely tied to instructional objectives. Today, the content of the test is informed by regular surveys of secondary school teachers and curriculum experts. The ACT consists of four multiple-choice sections: English, Mathematics, Reading, and Science. Test takers receive a score in each subject area, as well as a composite score and a “STEM score,” which is based on performance on the Math and Science sections. Those who choose to take an optional essay test in Writing receive a Writing score and an English Language Arts score based on the English, Reading, and Writing results.

The GRE

The Graduate Record Examinations program of the Carnegie Foundation for the Advancement of Teaching administered its first exam in 1937. In 1948, the GRE program was transferred to ETS, which had been founded the previous year. Today, the GRE is developed and administered by ETS under the direction of the GRE Board, an independent organization that is affiliated with the Association of Graduate Schools and the Council of Graduate Schools. Although it is primarily used to evaluate candidates for admission to graduate school, the GRE General Test is accepted by some business schools and law schools as well. According

to the GRE Website, the test “measures skills that graduate and professional programs have identified as prerequisite for success at the graduate level. One such essential skill is critical thinking, and the GRE General Test measures aspects of critical thinking in each of the test’s three sections,” which are Verbal Reasoning, Quantitative Reasoning, and Analytical Writing. The General Test is computer-administered and is available in test centers around the world.

Since 2011, the Verbal Reasoning and Quantitative Reasoning sections of the GRE General Test have been administered as multi-stage tests (MSTs). In each of these areas, the first of two subsections is of medium difficulty, for purposes of routing. The test taker’s score on the routing subsection determines whether the second section will be easy, medium, or difficult (Robin et al., 2014). (A paper-delivered non-MST version of the GRE is offered in regions of the world where computer-based testing is unavailable).

At the time of the transition to MST format, the content of the Verbal, Quantitative, and Analytical Writing measures was revised, along with the scale on which Verbal and Quantitative scores are reported. The Verbal Reasoning section includes multiple-choice items and items that involve identifying a sentence in a passage that meets a certain description. The Quantitative Reasoning section includes multiple-choice items and those that require numerical entry, as well as quantitative comparison items, in which test takers must compare two quantities and determine whether one quantity is greater, the two are equal, or there is insufficient information to decide. Some multiple-choice items in both the Verbal and Quantitative sections require the test taker to select all correct answers from a set of possible responses, as more than one response may be correct. The Analytical Writing section consists of two essay tasks, which are intended to assess candidates’ ability to “to articulate and support complex ideas with relevant reasons and examples, and examine claims and accompanying evidence,” according to the GRE Website. Test takers receive separate scores in Verbal Reasoning, Quantitative Reasoning, and Analytical Writing.

In addition to the General Test, GRE Subject Tests in Biology, Chemistry, Literature in English, Mathematics, Physics, and Psychology are available, delivered in paper form.

The MCAT

The Medical College Admission Test, first given in 1946, is sponsored by the Association of American Medical Colleges (AAMC), which currently represents 172 accredited US and Canadian medical schools, more than 400 teaching hospitals, and various academic societies and medical professionals. (An earlier test, called the Scholastic Aptitude Test for Medical Students or the Moss Test, was administered between 1928 and 1946.)

The current version of the MCAT, launched in 2015, is a computer-administered, multiple-choice examination that, according to the AAMC Website, is “designed to assess ... problem solving, critical thinking, and knowledge of natural, behavioral, and social science concepts and principles prerequisite to the study of medicine.” The test consists of four sections: Biological and Biochemical Foundations of Living Systems, Chemical and Physical Foundations of Biological Systems, Psychological, Social, and Biological Foundations of Behavior, and Critical Analysis and Reasoning Skills. Test takers receive a score on each section, along with a total score.

The LSAT

The LSAT was conceived at a 1947 meeting between College Board staff and representatives of an association of nine law schools, the precursor of the Law School Admission Council (LSAC). In 1948, the first LSAT was administered by ETS. Since 1979, the LSAT has been administered by the LSAC itself, which today has 222 member institutions in the US, Canada, and Australia.

According to the LSAC Website, the test is “designed to assess critical reading, analytical reasoning, logical reasoning, and persuasive writing skills—key skills needed for success in law school.” The LSAT is administered in two parts. The first part of the test is a multiple-choice exam administered at test centers around the world. In North America, this portion is administered by computer. This part of the exam includes one Reading Comprehension section, one Analytical Reasoning section, and two Logical Reasoning sections. Performance is summarized in a single score.

The second part of the test, called LSAT Writing, is an unscored writing sample that is submitted online using secure proctoring software that can be installed on the candidate’s own computer. Test takers are given a decision problem and are asked to write an essay in which they choose between two positions and defend their choice. Copies of the writing sample are sent to all schools to which candidates apply.

The GMAT

In the late 1940s and early 1950s, the GRE was used to screen business school applicants. In 1953, however, representatives of nine graduate schools of business agreed that they needed an admissions test of their own and, just a year later, the precursor to the GMAT was administered (Schmoller, 1993). For five decades, the test was developed and administered by ETS for the Graduate Management Admission Council (GMAC). Since 2006, the GMAC has contracted with ACT, Inc. to develop the GMAT and with Pearson VUE, a company specializing in computer-based testing, to administer it.

The GMAT is a computer-administered test of “skills required to be successful in graduate business school,” according to the test handbook (Graduate Management Admission Council, 2020). It contains three multiple-choice sections—Verbal Reasoning, Quantitative Reasoning, and Integrated Reasoning, as well as an essay test, the Analytical Writing Assessment.

The Verbal and Quantitative Reasoning sections are adaptive, meaning that they are tailored to the test taker’s skill level. Each of these sections begins with a medium-difficulty item; the difficulty of subsequent items depends on the responses to previous items. The Integrated Reasoning section is the newest part of the test. Added in 2012, it measures the “ability to analyze data and evaluate information presented in multiple formats,” according to the GMAT Website. Many of the Integrated Reasoning questions require

more than one response, and an online calculator with basic functions is available for test takers to use. The Analytical Writing Assessment is intended to measure the ability to think critically and communicate ideas. GMAT test takers receive a score for each of the four sections of the test as well as a total score based on the Verbal and Quantitative sections.

The use of higher education admissions tests in the US

Use of admissions tests at four-year undergraduate institutions

In the US, use of admissions tests varies widely across institutions. In academic year 2018–2019, there were approximately 2300 four-year institutions offering degrees at the bachelor's level or higher. (Only schools that enrolled first-year undergraduates and participated in Title IV federal financial aid programs were included in this count). About 25% of these four-year colleges and universities were open-door, meaning that they accepted all applicants, 30% accepted at least three-quarters of their applicants, and 30% accepted between half and three-quarters. Only 14% had acceptance rates lower than 50% ([National Center for Education Statistics, 2020](#)). The US also has about 1300 two-year institutions, most of which are open-door and therefore do not use admissions tests.

According to the National Association for College Admission Counseling (NACAC), which conducts annual surveys of postsecondary institutions, “[t]he factors that admission officers use to evaluate applications from first-time freshmen have remained largely consistent over the past 20 years. Students’ academic achievements—which include grades, strength of curriculum, and admission test scores—constitute the most important factors in the admission decision” ([Clinedinst, 2019](#), p. 4). However, it is worth noting that the percentage of responding institutions attributing “considerable importance” to test scores declined from 52% to 46% between 2017 and 2018. (Because of the nature of the sample, some caution is warranted in interpreting the NACAC results. In 2019, NACAC surveyed its member institutions, which represented 78 % of four-year institutions in the US that met certain criteria. The response rate was 35% ([Clinedinst, 2019](#), p. 23)).

A recent trend that is not discussed in the NACAC report is the increase in test-optional admissions policies in the US. Under these policies, which began in a few small liberal arts colleges in the 1960s, college applicants themselves decide whether to submit admissions test scores. Submitters’ scores are considered in the admissions process, but nonsubmitters are not at a disadvantage. The National Center for Fair & Open Testing, better known as FairTest, keeps track of schools that do not require admissions test scores. As of late 2020, the organization’s website includes a list titled, “1600+ Accredited, 4-Year Colleges & Universities with ACT/SAT-Optional Testing Policies for Fall, 2021 Admissions” (see <https://www.fairtest.org/university/optional>).

The test-optional movement gained steam in the early 21st century. In most cases, institutions adopting test-optional policies did so in the hope that a more diverse student body would result ([Lopez et al., 2020](#)). The movement grew stronger in the wake of the coronavirus pandemic that struck in 2020. Because most test centers closed, many institutions waived test score requirements—in some cases, for multiple admissions cycles ([Jaschik, 2020](#)).

Use of admissions tests at graduate and professional schools

Graduate school programs tend to be smaller, and admissions policies much more flexible than at undergraduate institutions. Admissions policies and rates vary widely over the hundreds of fields of graduate study available in the US. Decisions are typically in the hands of program faculty, rather than admissions officers and admission rates tend to be much lower.

Surveys have shown that standardized admissions tests are widely used in graduate admissions, in combination with undergraduate grades and other factors ([Kuncel et al., 2001](#)). According to the GRE website, the GRE General Test “is accepted at thousands of graduate schools, including business and law.” In recent years, however, there has been a growing concern that an overemphasis on GRE scores could constitute a barrier to campus diversity (e.g., see [Posselt, 2016](#)). Some graduate departments, therefore, have elected to eliminate the requirement to submit admissions test scores and have moved toward more holistic reviews of applications.

Use of admissions tests is nearly universal at professional schools. The MCAT is required by almost all US medical schools and many Canadian medical schools, the GMAT is used by more than 2300 schools of business and management, according to its website, and the LSAT is the “only test accepted for admission purposes by all ABA [American Bar Association]-accredited law schools and Canadian common-law law schools,” according to its website. (An ABA standards document states that “[a] law school shall require each applicant ... to take a valid and reliable admission test ... A law school that uses an admission test other than the [LSAT] shall demonstrate that such other test is a valid and reliable test ...” ([American Bar Association, 2020](#)). The document provides for some exceptions to this rule). Undergraduate grades are also considered very important in professional school admissions, and medical schools place a high value on interviews as well ([Monroe et al., 2013](#)).

Predictive validity of admissions tests

College, graduate school, and professional school admissions tests are intended to be useful for predicting the grades students will receive in the educational programs they enter. Although a comprehensive evaluation of a test’s validity must involve a consideration of the test’s design, development, content, administration, and use, the validity of admissions tests as a selection tool for higher education institutions is, in practice, judged largely by the degree to which test scores can predict students’ grade-point averages in college, graduate school, or professional school (GPAs). Most often, first-year grades are used.

Conducting a predictive validity study requires that the GPAs for the cohort of interest be available so that the predicted GPAs can be compared to the GPAs actually earned by the admitted students. Predictive validity studies are usually conducted within a single institution, although results may later be averaged across institutions.

Linear regression analysis is typically applied to estimate an equation for predicting college, graduate school, or professional school GPA. The usual predictors are admissions test scores and high school grades (in the case of college admissions) or undergraduate grades (in the case of graduate or professional school admissions). The resulting multiple correlation, which can range from 0 to 1, provides an index of the effectiveness of the prediction equation. The regression analysis can then be repeated using prior grades alone as a predictor. Comparing the predictive effectiveness of the two equations yields an estimate of the value added by using admissions test scores. The simple correlations between test scores and subsequent GPAs are often examined as well.

A factor that complicates the interpretation of these correlations, or validity coefficients, is restriction of range: students whose test scores are too low to allow admission to a higher education institution will not have GPAs. Because of this restriction of range (of test scores, and, as a result, of other predictors and of GPAs as well), validity coefficients tend to be smaller for the admitted students than they would be for the entire population of applicants. Statistical corrections are often applied in an attempt to estimate how big the association would have been if the range had not been restricted (see Gulliksen, 1987: 165–166). In addition, corrections are sometimes applied to adjust for *criterion unreliability*, which is the imprecision of the measure that is being predicted. Except where noted, the correlations reported in this article have not been corrected in any way. Typically, corrected correlations are larger by 0.15–0.20.

A recent review of the predictive validity of admissions tests in college, graduate school, and professional school (Camara et al., Manuscript in preparation) reveals some consistent patterns in the findings. For both the ACT and the SAT, the correlation with college GPA was recently found to be 0.51 in large-scale studies after corrections were applied (Marini et al., 2019a; Westrick et al., 2021). In the case of the ACT, these results are based on analyses of the ACT composite score. In the case of the SAT, results are based on the total of the Math and Evidence-Based Reading and Writing scores. The correlations between admissions test scores and college GPA were somewhat lower than the correlations between high school grades and GPA, which were found to be 0.61 for ACT takers and 0.53 for SAT takers. Analyses that included admissions test scores as predictors along with high school grades yielded multiple correlations with GPA of 0.61 for the SAT (Marini et al., 2019a) and 0.64 for the ACT (Westrick et al., 2021).

In separate studies, the optional SAT Essay (no longer offered) was found to add useful information above and beyond the SAT Evidence-Based Reading and Writing section score in predicting college GPA (Marini et al., 2019b) and the optional ACT Writing test was found useful for predicting grades in entry-level college English composition courses (Radunzel, 2019).

Only a few studies have investigated the validity of the current version of the GRE, introduced in 2011, for predicting graduate school performance. In one such study, Schwager et al. (2015) evaluated the utility of GRE scores and undergraduate GPA as predictors of academic performance in a Dutch university. The research was based on a sample of 282 international student volunteers who took the GRE after they had already been admitted to master's programs. GRE scores were found to improve the prediction of final graduate school GPA beyond the level of accuracy attained with undergraduate GPA alone. Corrected correlations were 0.21 for Verbal Reasoning, 0.17 for Quantitative Reasoning, 0.31 for Analytical Writing, and 0.21 for undergraduate GPA.

Liu et al. (2016) studied the predictive validity of the GRE General Test based on data from more than 3000 students who enrolled in graduate study at the National University of Singapore between 2011 and 2014. Correlations between GRE scores and first-year graduate school GPA were 0.20 for Verbal Reasoning, 0.32 for Quantitative Reasoning, and 0.14 for Analytical Writing. These values were obtained using the combined data for master's and doctoral programs, with correction for range restriction. These correlations exceeded the correlation between undergraduate GPA and graduate school GPA.

Zimmerman et al. (2017) studied the validity of the GRE General Test for admission to master's programs at a technical university in Western Europe. Data was collected between 2006 and 2013; therefore, only a portion of the sample had taken the most recent version of the GRE. Concordance tables were used to place all GRE scores on a common scale. Based on a sample of 369 students, correlations with graduate school GPA were found to be 0.33 for Verbal Reasoning, 0.17 for Quantitative Reasoning, 0.30 for Analytical Writing, and 0.16 for undergraduate GPA.

Additional studies have led to favorable conclusions about the utility of the GRE as a predictor of performance in law school (Klieger et al., 2018) and in business school (e.g., Young et al., 2014).

In their review, Camara et al. (Manuscript in preparation) cite recent validity findings for the GMAT, LSAT, and MCAT. The GMAT total score (Verbal plus Quantitative) was found to have a correlation with graduate school GPA of 0.38, compared to 0.32 for undergraduate GPA. For the Integrated Reasoning and Analytical Writing sections, median correlations of 0.27 and 0.13, respectively, were reported, and a correlation of 0.51 was obtained when all four GMAT sections and undergraduate GPA were used as predictors (Talento-Miller, 2017). For the LSAT, the correlations with graduate GPA were 0.38 for LSAT score, 0.26 for undergraduate GPA, and 0.47–0.48 for both predictors combined (Anthony et al., 2016), and for the MCAT, a recent study found that the median corrected correlation over 16 schools was 0.57 for MCAT Total, 0.52 for undergraduate GPA, and 0.65 for both predictors combined (Busche et al., 2020).

In summary, college admissions test scores tend to be slightly weaker than high school grades as predictors of college GPA, but including test scores in addition to past grades in the prediction equation increases the correlation coefficient. (An exception to this pattern is a large study at the University of California that found that “[a]t UC, test scores are currently better predictors of first-year GPA than high school grade point average” (University of California Academic Senate, 2020: 20)). In recent research, test scores have been found to be more effective than undergraduate grades in predicting graduate school and professional school grades.

Although first-year GPA is the most common criterion variable in admission test validity studies, other criteria have been studied as well. For example, there is considerable evidence that admissions test scores are helpful in predicting grades beyond the first year (Kuncel and Hezlett, 2007; Zwick, 2006, 2007). The evidence on prediction of degree attainment is mixed (Zwick, 2006, 2007). The ACT and SAT appear to be useful for this purpose (e.g., Radunzel and Noble, 2012; Mattern et al., 2013), while graduate and professional school admission tests are less so (Kuncel and Hezlett, 2007). Some studies have examined prediction of other criteria, such as performance on licensing exams and measures of career success, with inconsistent results (see Zwick (2006) for a summary).

Use of personal characteristics to predict success in higher education

An area of ongoing debate is whether including formal measures of personal characteristics (sometimes called noncognitive factors) could improve the prediction of success in higher education while simultaneously making the admissions process more equitable. In a landmark 1985 study, Warren Willingham identified a characteristic he called “productive follow-through,” defined as “persistent and successful extracurricular accomplishment” in high school. Productive follow-through proved to be a poor substitute for high school grades and admissions test scores in predicting which students would be identified as most successful by their colleges, but taking this quality into account along with traditional academic qualifications substantially improved the prediction of success (Willingham, 1985: 184).

The question of whether measures of personal characteristics should be included in college admission decisions, however, is far from straightforward. The use of such characteristics can, intentionally or unintentionally, lead to the exclusion of certain demographic groups (Zwick, 2017a). In addition, personal characteristics are hard to measure in a fair and accurate way. One limitation in using self-reports about these attributes in the admissions context is that the desired answers are often obvious to the respondent. Another drawback is that some measures of these characteristics have shown patterns of group differences similar to those typically seen on standardized tests, on which white students tend to receive higher scores than other students (Zwick, 2017b). Other measures have been shown to have little or no power to predict college performance (e.g., see Thomas et al., 2007: 648).

Although there is widespread agreement that factors such as perseverance, grit, and ability to delay gratification are relevant to success in higher education, measuring these characteristics accurately and without bias is difficult. Thus, relying on observable evidence of the desired characteristics (such as the completion of a long-term research project) or on information from respondents other than the candidates themselves (possibly in the context of a standardized letter of recommendation) may yield more useful data.

Fairness of admissions tests to people of color, women, and other special populations

Standardized admissions test results often reveal substantial average score differences across ethnic, gender, and socioeconomic groups. Among the general public, these differences are often regarded as sufficient evidence that these tests are biased. From a psychometric perspective, a test’s fairness is inextricably tied to its validity. According to Cole and Moss (1989), test bias occurs (i.e., fairness is violated) “when a test score has meanings or implications for a relevant, definable subgroup of test takers that are different from the meanings or implications” for other test-takers. “... [B]ias is differential validity of a given interpretation of a test score ...” (p. 205).

Psychometric assessment of the fairness of admissions tests typically comprises two broad types of investigations. One type consists of analyses of differential prediction of a criterion, usually a GPA. Two distinct questions are typically addressed: first, are the test scores equally predictive of later grades for all groups? This question is typically investigated by obtaining separate prediction equations for each group and then comparing correlation or regression coefficients across groups. Second, if we obtain a single prediction equation for students as a whole, does this equation produce predicted GPAs that are systematically too high or too low for some groups? (See Zwick, 2017b).

Another common component of fairness assessment is an examination of item content. Before a test question is approved for inclusion in an admissions test, it undergoes a “sensitivity review” to eliminate any content that may be disturbing or offensive to test takers. Later, after the test is administered, a differential item functioning (DIF) screening is performed to determine whether equally skilled members of different groups (e.g., men and women) have statistically different rates of correct response on some items. The purpose of DIF analysis is to identify test items with content that may be problematic for some student group. For example, the item may include content that is irrelevant to the construct being assessed, and is more familiar to some student groups than others, such as sports content in a mathematics test. Items found to have DIF are either discarded immediately or flagged for further study.

Zwick (2012) summarizes findings on differential prediction of GPAs for key student groups, including people of color, women, people with disabilities, and students with limited English skills, provides a discussion of DIF findings, and addresses fairness issues associated with test coaching.

A sampling of higher education admissions testing around the world

Higher education admissions processes vary internationally in terms of the degree of government oversight, the degree of centralization, and the role, if any, of admissions tests. Some examples follow.

University admissions in China is based on a highly competitive government-controlled system that relies almost entirely on the National College Entrance Examination, or gaokao (Reshetar and Pitts, 2020). The 9-hour test, which is administered annually, is

typically taken by students in their last year of high school. Each provincial administrative region is assigned an admissions quota; provincial administrators then determine the minimum gaokao score required for admission to each tier of Chinese universities for candidates from that province. Prospective students may only apply to universities in tiers for which they exceed the minimum score. Admissions decisions are made based on additional score requirements associated with each university and program (Zhang and Wang, 2018).

There are two versions of the gaokao—one for students who want to study scientific fields and one for those who wish to pursue studies in the social sciences. All students must respond to sections in Mandarin Chinese, Math, and a foreign language. Those taking the natural sciences exam complete additional sections that may include Physics, Chemistry, or Biology, while those taking the social sciences exam complete sections that may include Political Sciences, History, or Geography (Reshetar and Pitts, 2020). The composition of the gaokao has been in flux in recent years and the Chinese Ministry of Education has reported that some students now have the opportunity to choose “new subject combinations instead of following the former mandatory path of either liberal arts or science” (Gaokao Reform, 2018).

Two major controversies in Chinese university admissions in the last decade have involved the exclusive focus on test scores in admissions and the under-representation of residents of particular provinces (Zhang, 2010). According to the Chinese Ministry of Education, some experimental admissions programs have taken into account students’ past academic achievements along with their gaokao scores. The Ministry also reports an increase in the admission of “rural and underprivileged students” (Gaokao Reform, 2018).

In Sweden, the admissions process for all public institutions (which constitute 30 of the 47 postsecondary institutions) is regulated by the government (Lyrén and Wikström, 2020). A distinction is made between eligibility requirements and selection criteria. In order to be admitted, all applicants must meet eligibility requirements; selection criteria are imposed only when a program has more eligible applicants than there are spaces. Eligibility is typically achieved by successfully completing secondary school. Selection may be based on upper-secondary-school grades, scores on the Swedish Scholastic Aptitude Test (SweSAT), or institution-specific requirements. While there are some exceptions, government regulations require that each institution select at least one-third of its students on the basis of grades and at least one-third on the basis of SweSAT scores. In practice, institution-specific requirements are rarely used (Lyrén and Wikström, 2020). The SweSAT consists of a Verbal section, which includes vocabulary; Swedish reading comprehension; sentence completion; and English reading comprehension, and a Quantitative section, which includes mathematical problem-solving; quantitative comparisons; data sufficiency; and diagrams, tables, and maps. Various proposals to reform Sweden’s eligibility and selection policies are currently under consideration.

In Israel, admission to higher education is generally based on two criteria—the Bagrut Certificate, or BC, administered by the Ministry of Education, and the Psychometric Entrance Test (PET), developed and administered by the National Institute for Testing and Evaluation, an independent body governed by the leaders of Israel’s research universities (Allalouf et al., 2020; Beller, 2001). The BC is the average score on tests administered by the Ministry and assessments conducted within the applicant’s high school. The PET, which is available in Hebrew, Arabic, English, and five other languages, contains sections in Verbal Reasoning (including an essay), Quantitative Reasoning, and English as a foreign language. National concerns about the fairness of the PET to various groups and the possible advantages of test coaching parallel those in the US. In response to social concerns about the admissions process, some alternate routes have been developed for use in certain cases, such as the admission of the top five percent of students in a high school or the inclusion of noncognitive tools or interviews (Allalouf et al., 2020).

Chile has a centralized national admissions system that is used to select studies for nearly all public and private universities. All applicants must take the national admissions test, the Prueba de Selección Universitaria (PSU) and submit a rank-ordered list of up to ten programs to which they wish to apply. A matching algorithm is used to assign students to programs, based on their PSU scores, high school grades, and rank in high school. The PSU consists of two mandatory tests—Language and Math—and two optional tests in Social Science and Science (which, in turn, involves a choice among Biology, Physics, and Chemistry). Program requirements determine which of these optional tests an applicant must take. Recently, the PSU has been the subject of major protests, mainly because of its perceived unfairness to students who participate in the technical-professional curriculum in high school rather than the scientific-humanistic curriculum (Koljatic and Silva, 2020). Various test reforms have been proposed, but their future is unknown.

Introduction to ITS

The origins of ITSs can be traced back to the 1950s and what is known as Computer Assisted Instruction, or CAI, which refers to the use of computers in the field of education. It was the introduction of “intelligence” to CAI in the 1970s that paved the way for a new genre known as ITS (Ahuja and Sille, 2013; Corbett et al., 1997). An ITS is a computer program that uses computational techniques to provide personalized instruction to students. This modern day intelligent tutor “knows” what to teach and, in theory, how best to do so. Perhaps most importantly, the tutor knows who is being taught, including their knowledge level, the misconceptions they may hold, their skills and abilities, and in some cases, their motivation and affective state. Research and development of ITSs weave together ideas from three different disciplines, including, computer science, education, and psychology (Alkhatlan and Kalita, 2018; Nwana, 1990). The interconnection between the three disciplines has advantages in terms of the breadth of research questions that can be conducted, which in turn, can contribute to advances in ITS technology. However, there also have been some disadvantages noted, namely that researchers need a firm grasp on all the relevant disciplines, and that those of different backgrounds may have competing goals, varying foci, and disagreement on frameworks and terminology (Nwana, 1990). Nonetheless, this area has generated technological innovations that have begun to successfully bridge the gap between human and computer when it comes to tutoring in education.

An important milestone in ITSs was when the target in terms of efficacy for student learning was set by a classic study by Bloom (1984), when he demonstrated that students who were guided by a human tutor performed two standard deviations better than those who studied in a traditional classroom or group learning environment. This quickly became the goal of ITSs in terms of efficacy at improving students’ learning.

A number of meta-analyses have been conducted on the effectiveness of ITSs, since this is critical to their improvement (Kulik and Fletcher, 2016; Ma et al., 2014; VanLehn, 2011). For example, VanLehn (2011) compared the effectiveness of human tutoring, computer tutoring, and no tutoring, and found that ITSs can be nearly as effective as human tutors.

Ma et al. (2014) also conducted a meta-analysis to compare the learning outcomes of students who used ITSs and those who did not; here other factors such as type of ITS, instructional setting (individual, small group, etc.), and subject domain (math, physics, etc.) were included. In this meta-analysis, it was found that a learning environment that included an ITS was more effective than teacher-led or large group instruction, non-ITS computer-based instruction, and textbooks or workbooks. Further, positive effect

sizes were found at differing levels of education, across different domains, and for different types of ITSs. Notably, however, no significant difference was found between ITS use and individual human tutoring or small group instruction. In another meta-analytic study by Kulik and Fletcher (2016), for 92% of the 50 studies examined, students who used ITSs outperformed students who did not. Further, the use of ITSs raised test scores, whether they were locally developed or standardized, over conventional classroom teaching environments. Thus, meta-analyses such as these provide evidence that suggests that ITSs can be effective at helping students learn.

Core components of ITS

It is widely accepted that typical intelligent tutoring systems (ITS) have four basic components (Corbett et al., 1997; Nwana, 1990). The *domain model*, also known as the expert model or cognitive model, which represents the knowledge, facts, concepts, and rules that belong to the domain being taught (e.g., physics or mathematics). The *student model*, which represents the students' knowledge, including the cognitive and, in some cases, the affective states of the students while they interact with the tutoring system. As the student responds to questions and solves problems, this information can be used to construct appropriate feedback. The *tutoring model*, also known as the pedagogical or teaching model, devises instructional strategies that can be used to provide customized feedback to students by integrating information from the domain/expert model and the student model. For example, the tutoring model can initiate actions, such as giving a hint to the student. Finally, the *user-interface model* is the interactive environment that the student uses to engage the system. It includes the graphics, text, and multimedia sources available to the student and presents the available actions a student can take during the tutoring process. Later in the entry we will provide linkages between each of these (domain model, student model, etc.) and Inq-ITS (Inquiry Intelligent Tutoring System, inqits.com; Gobert et al., 2013, 2016, 2019; Mislevy et al., 2020), where relevant, for illustrative purposes.

History of ITS

Computer-assisted instruction

In its earliest stage, CAI was based on the work of B.F. Skinner and his principles of operant conditioning (Skinner, 1948). In a Skinnerian system, a student was presented with simple questions and then given the correct answer. The goal was to lead the student toward a desired end behavior. The series of "frames" were presented regardless of correctness because wrong answers did not help students learn the correct behavior, according to Skinner. In a frame-oriented system like this, designed to proceed regardless of how the student responds, there is a lack in the capacity to provide any personalized feedback, which later systems compensated for (Nwana, 1990). Further, in this linear style, all of the questions and answers had to be pre-determined, and as such, may not provide appropriate or helpful responses for students (Rickel, 1989).

In the 1960s, Crowder (1959) introduced branching, or intrinsic programs that no longer ignored student responses. Instead, they were used to determine the next frame to be presented to a student (Edwards, 1968; Nwana, 1990). In intrinsic programs, each response to a multiple-choice question is linked to another page in the program. When the student responded with the correct answer, they were presented with subsequent information. If the student selected the wrong choice, they were taken to a page that explained why that choice was incorrect, and then were prompted as needed to retry with a similar question (Edwards, 1968). These branching types of ITSs were also limited as students were confined to multiple choice questions and given no robust feedback, critical to improving learning.

Emerging in the late 1960s and early 1970s, generative systems elucidated and implemented the idea that tutoring material could be generated by the system itself; this soon followed as an improvement to the limited, step-wise nature of frame-oriented systems. Generative systems work by using textual templates, problem-generation grammars, and random numbers so the system can supply as many problems or examples as a student might need to improve learning (Nwana, 1990). An early example is Wexler's system, in which information is encoded in a network and then used to generate new questions and responses (Nwana, 1990; Rickel, 1989). Wexler grouped objects into classes that could then be linked to other classes, such as "family," which could be linked to "mother, father, and children" (Rickel, 1989). These systems were still insufficient however, in that they failed to interact with or adjust to the student's needs and responses. Moreover, they were restricted to drill-type exercises in well-defined domains such as mathematics that have structured content with objective answers (Nwana, 1990; Rickel, 1989). Further, generative systems have an inadequate representation of the students' domain knowledge, making it difficult to tailor feedback in a personalized or adaptive manner (Nwana, 1990; Rickel, 1989).

In early CAI, the student model component used in typical ITS architecture often lacked fine-grained user information and the functionality to provide an adaptive and personalized tutoring experience, which is ultimately the goal of ITSs. In one example, namely, the Leeds Adaptive Arithmetic System (Nwana, 1990), a rudimentary attempt at fulfilling the student model involved using a single integer to represent a student's competence level. In another example of an ITS with a simple student model, the KEYSTROKE model was able to determine the productivity of a user by counting their keystrokes in a basic task such as searching for information (Sleeman, 1985). Another issue, according to Sleeman, is that many early systems did not distinguish an expert from a novice in a given subject area and thus, did not lead to effective tutoring. Sleeman acknowledged that student modeling is an open-ended task and thus requires a system with the capability to interpret and respond to the diverse

knowledge, skills, and abilities of students; however, in well-defined domains, the system can make more simplified assumptions about a user than in ill-defined domains. Later in the chapter we provide a more detailed section on student modeling, as it is a key factor in ITS development and efficacy in supporting students' learning.

From CAI to ITS

With a lack of fine-grained user knowledge (i.e., student model) in early CAI systems, experts soon realized the potential gains of incorporating "intelligence" into these systems. Self (1974) argued that to be most effective, CAI should include a representation of what is being taught, who is being taught, and how to teach it. These categories, respectively, correspond to the current ITS architecture of the domain model, student model, and tutoring model. These improved systems have a more sophisticated representation of the student model, one in which the current knowledge state is used to determine appropriate and personalized instruction (Rickel, 1989).

The first intelligent tutoring program, known as SCHOLAR, marked the introduction of AI to CAI, and ushered in a new generation of systems, which then became labeled as Intelligent Tutoring Systems (Nwana, 1990). SCHOLAR engaged students in dialog, allowing them to ask and answer questions (Carbonell, 1970). This system used a semantic network of units, which form a complex network of facts, concepts, and in some cases, procedures (Ahuja and Sille, 2013). Nodes in the network were tagged if the student recognized a concept. Further, this system exemplified a mixed-initiative approach, whereby the student as well as the tutor could ask (initiate) questions and dialog (Shute and Psotka, 1994). Since this system used a natural language dialog, if the system did not understand the student's question or response, the learning process was halted.

ITS developments from the 1980s to present

Buggy-based approach

By the 1980s, ITS development grew and various systems were developed with different foci in mind. One example is the buggy approach (Brown and Burton, 1978), which not only identifies a student's misconceptions, or bugs, but helps to explain why a student is making a mistake. One demonstration of a system based on the buggy approach is PROUST (Johnson and Soloway, 1985), which targets errors in students' computing of descriptive statistics, such as calculations of range and averages (Shute and Psotka, 1994). A report is submitted to PROUST after the student completes the program, and then the system locates errors and sends a diagnostic report (Shute and Psotka, 1994).

Model tracing

Another approach involves model tracing in which the system tracks a student step-by-step during a problem solving task and then compares this to the expert domain to provide personalized feedback as the student progresses (Merrill et al., 1992). The objective is to sequence the student's problem-solving actions within a complex problem space that may contain thousands of solutions (Corbett et al., 1997). One criticism of model-tracing, however, is the frequent interference from the tutor, which can limit a student's opportunity to learn from or reflect on his own mistakes (Merrill et al., 1992).

Case-based reasoning

Case-based reasoning (CBR) also appeared in the 1980s, which involves applying prior experiences and memories, or cases, to new information in order to interpret problems and find solutions (Kolodner, 1992). This can be applied to the human reasoning process as well as in the approach and design of ITS systems. Kolodner (1983) introduced the first CBR system, known as CYRUS, which is an intelligent fact retrieval system that stores and retrieves events of former Secretaries of State, Cyrus Vance and Edmund Muskie. If given a new fact, it will organize it within the existing database and can also call up a fact when asked, such as "When was the last time Vance was in Egypt?". Another example is CHEF, which created new recipes from recipes it already knew. By accessing a recipe with chicken and peas, it was able to substitute beef and broccoli and adjust the steps in the directions accordingly (Kolodner, 1992). Case-based reasoning has the potential to provide a more adaptive learning environment because it suggests approximate answers rather than providing an absolute response. This also makes it more suitable for ill-defined domains (i.e., philosophy), or environments in which there are too many rules or a rule that can be applied in many ways, such as game playing or programming (Ahuja and Sille, 2013; Shute and Psotka, 1994). Science inquiry is another ill-defined domain, and will be addressed later in the entry (Gobert et al., 2013).

Natural language processing

Another focus of development in ITSs in the 1980s was Natural Language Processing (NLP; Burstein, 2009; Burton, 1976; Chowdhury, 2003). NLP research has helped create a more natural flow in communication between a human and machine, or student and tutor by gathering information about how humans use and understand language and then using it to interact with the user (Chowdhury, 2003). An early example of a system built on NLP is SOPHIE (Burton, 1976), which applied semantic grammar techniques in a well-defined domain. SOPHIE's expert domain was electronic troubleshooting, which simulated faults on which the student could apply their theoretical knowledge to form hypotheses and attempt experiments to troubleshoot the problem (Nwana, 1990).

Discovery worlds and simulations

Another product of ITS development throughout the 1980s was discovery worlds (Abuja and Sille, 2013) or simulations. A simulation is a model of scientific (or social) phenomena that represents the domain-specific properties and conceptual representations of that phenomena. A simulation may emulate some features of real phenomena but not others. Originally referred to as micro-worlds by Papert as a "... subset[s] of reality or a constructed reality so ... as to allow a human learner to *exercise* particular powerful ideas or intellectual skills" (Papert, 1980, p. 204). For example, digital simulations enable learners to change aspects of phenomena, i.e., speed up, slow down, change size, or simplify aspects of real-world phenomena. Learners can explore phenomena, which are not possible to explore in real life due to their size and or time scale (Gobert and Clement, 1999), or engage in due to safety issues.

The goal with simulations is for students to use a computer simulation environment to learn content and skills on their own (Shute and Psotka, 1994). The notion of student-led discovery, however, is at odds with an ITS since the goal of ITS is to provide feedback to guide students' learning. For example, White (1984) created a system that allowed students to explore Newton's laws of motion in a discovery world (a simulation) by controlling a spaceship and navigating it toward a target or through a maze. While these types of systems allow for more freedom on the part of the student to guide their own learning processes, it does demand some knowledge and skill to operate within the microworlds. Students must know what to manipulate and how to do so, i.e., design an experiment or support a hypothesis, etc. (Shute and Psotka, 1994).

Mental models

Related to discovery worlds and simulations is the psychological construct invoked to describe the form of the cognitive representations that are constructed when learners engage in deep learning (Johnson-Laird, 1983). More specifically, model-based learning assumes that understanding requires the construction of mental models of the phenomena under study, and that all subsequent problem-solving, inferencing, or reasoning are done by means of manipulating or "running" these mental models (Gobert and Buckley, 2000). Using the notion of mental models, the 1980s saw systems that leveraged progressively more complex causal models presented in ITSs to, in turn, support the development of students' mental models (Abuja and Sille, 2013). These systems, like QUEST (Qualitative Understanding of Electrical System Troubleshooting; White and Frederiksen, 1990), point out errors in students' thinking and guide students through increasingly complex microworlds. They then allow students to test their ideas by applying the set of laws to see if it predicts real-world events (Shute and Psotka, 1994).

Virtual reality

Going beyond simulations are more deeply immersive-type environments called virtual reality, another innovation in ITSs during the 1990s. These were influenced by situated learning, which emphasized the importance of the physical (and social) context on students' learning processes (Brown et al., 1989). With virtual reality, users can experience a simulated 3-dimensional environment in which they can move about and manipulate aspects of the environment to learn about phenomena as well as new skills (Shute and Psotka, 1994). Virtual reality provides learning opportunities and experiences in a similar manner to simulations, i.e., experiences that would otherwise not be possible or feasible. For example, Perez-Valle and Sagasti (2012) developed a system that allowed students to visit 16th century Spain and tour buildings and temples that no longer exist.

Learner control

Moving into the 1990s, one major issue among researchers in ITS development centered on the topic of learner control. On one side of the issue are those who believe the learners should be in control of their learning processes, while others believe that structure and guidance are necessary components to a learner's success. When applied to the field of ITS, more learner control equates to a learning environment in which students can explore without many restraints imposed by the system. In a program called Smithtown (Shute and Psotka, 1994), which teaches basic microeconomics, students can explore the environment freely and then design their own experiments by choosing variables, testing a hypothesis, and analyzing their data. The system provides a notebook and table to collect and organize data, and graphing tools to allow students to plot their data. For example, students can select a market to explore, such as gasoline, and then adjust the price, and analyze the effects on the market by making a graph reflecting the supply and demand (Shute et al., 1988). In science, the degree of learner versus system "control" used to guide students' activities in learning environments, particularly those involving simulations and/or microworlds, is a topic that has been hotly debated (Hmelo-Silver, 2004; Kirschner et al., 2006). Some have encouraged open-ended exploration by students, and others have offered guidance or structure within the microworld to promote optimized learning. Later, we describe how Inq-ITS scaffolds students by both structuring inquiry into phases and using hints provided by a virtual tutor to help the student when the system detects that the student is struggling with a particular inquiry competency.

Collaborative learning

Further research in education and technology suggested collaborative learning can also enhance learning outcomes in the context of ITSs, which became another focus of ITS development in the 1990s (Alkhatlan and Kalita, 2018). There are certain characteristics that must be in place to achieve success in a collaborative learning group, such as participation and performance analysis (Soller, 2001). For example, in one such system for learning fractions, students could use audio chat to talk through the problem; students were also assigned roles such as helper or problem solver to guide them through the interaction and promote accountability (Olsen et al., 2014).

Tutoring for affective states and engagement

By the end of the 1990s, an emphasis on the emotional state of the learner became a new focus of ITS development. This was in part due to the hypothesis that engagement can influence learning (Gobert et al., 2015). Further, by being able to infer the emotional state of the learner, the system can then respond more appropriately to the needs of the student both cognitively and psychologically (Picard, 1997). For example, student engagement can be tracked via logfiles, which are fine-grained traces of students' interactions in a learning environment for science (Gobert et al., 2015). There also exist various methods to capture the affective state of the student including a computer's camera and microphones, specialized mice, and neuro-headsets, which collectively provide feedback regarding a student's facial expressions, voice, and physiological measures such as heart-rate and skin-conductivity (Alkhatlan and Kalita, 2018; D'Mello and Graesser, 2009). For example, in Auto-Tutor, a natural language ITS that has been used in domains such as computer literacy and physics, three sensors monitored students' affective state using posture patterns, videos of their face, and audio of their speech. This data was used to detect and differentiate emotions such as boredom, delight, and frustration (D'Mello and Graesser, 2009), and in turn was used to devise a targeted response, such as presenting an engaging task if the system detected a student's boredom. For more information on engagement and affective tutoring, see Andres et al. (2021), Baker et al. (2021), Henderson et al. (2021), Lester et al. (2019), and Mott et al. (2021).

Game-based ITSs

One of the more recent developments regarding ITSs is that of game-based learning, which also presupposes that students will learn more effectively if they are more deeply engaged in learning (Alkhatlan and Kalita, 2018). Though, a more apt statement in our opinion is that engagement is a *necessary but not sufficient condition* for learning, since deep learning is influenced by a variety of factors (Gobert, 2022). Rai and Beck (2012) created a math tutoring system with game-like elements, such as naming the monkey character students interact with or receiving badges after completing a level of learning. Despite many benefits to game-based systems, such as maximization of student participation, there also exist potential drawbacks associated with these types of systems (Alkhatlan and Kalita, 2018). Games often demand high cognitive load of users, which can lead students to feel overwhelmed and, in turn, diminish long-term learning of the material (Rai and Beck, 2012); this focus may be better utilized on content rather than the dynamics of the game.

Student modeling

Earlier we highlighted the core components of ITSs, including the student model. It is important to note that the adaptability and personalization of an ITS ultimately relies on the construction of an effective student model. By this, we mean that the student model leads to an understanding of the user by drawing on relevant information including a student's performance, misconceptions, prior knowledge, and in some cases, their personality characteristics. In brief, there are a number of approaches to building a student model including the overlay model, perturbation model, machine learning, cognitive theories, fuzzy logic, and Bayesian networks, with most ITSs using some combination of these (Chrysafiadi and Virvou, 2013), though it is beyond the scope of this entry to articulate the differences between all of these development approaches.

Three approaches that are noteworthy due to their popularity in the development of ITSs are the overlay model, stereotype model, and perturbation model (Chrysafiadi and Virvou, 2013). The overlay model was developed by Stansfield et al. (1976) and views the student's knowledge as a subset, or overlay, of the expert's knowledge, as represented by the domain model. The focus of the ITS then, is to minimize the gap in knowledge between the expert's and the novice's knowledge, skills, etc. (Alkhatlan and Kalita, 2018). The perturbation model is often viewed as an extension of the overlay model because it in part is a subset of the expert's knowledge, but unlike the traditional overlay model, it incorporates misconceptions or incorrect beliefs into this knowledge gap (Alkhatlan and Kalita, 2018). The stereotype model categorizes students based on shared characteristics, or stereotypes in order to guide them through an appropriate task or level based on their current knowledge state. An ITS may classify a new user into a category based on their level of knowledge about the content and can then infer information about the user based on other shared characteristics of that particular stereotype (Chrysafiadi and Virvou, 2013).

There are certain drawbacks, however, to each of these approaches. The overlay model is limited in that it does not take into account the learner's behavior and personality characteristics or the way users integrate new information. The perturbation model has demanding computational requirements and is limited in that the predetermined "bugs" in the system may not apply to some students. The stereotype model is inflexible in that the stereotype classes are pre-set by the system designer, which is time-consuming, and the users must be "of a type" that allow for discrete categorization in order to apply the stereotypes (Chrysafiadi and Virvou, 2013).

Machine learning/data mining

Through the early 2000s, the overlay, stereotype, and perturbation models were the most popular student modeling approaches. However, due to the limitations described above, a newer more adaptive and automated approach, known as machine learning or data mining, gained momentum (Chrysafiadi and Virvou, 2013). Though the term dates back to the 1980s, by the early 90s it was viewed as a sub-process of Knowledge Discovery in Databases or KDD (Coenen, 2011). Machine learning fulfills the need to automate the processes by which a user's actions and behaviors can be observed (Chrysafiadi and Virvou, 2013; Luan et al., 2020). Machine learning analyzes large amounts of data in order to extract meaningful information (Baker and Yacef, 2009; Coenen, 2011), and its techniques allow for better construction and greater adaptability of the student model (Ahuja and Sille, 2013). In the 1990s, machine learning saw a decline and then a resurgence because of the need for large data sets, labeled data, and

computational complexity (Webb et al., 2001). Presently, machine learning is increasingly used for the explanation, prediction, and description of student behavior (Yang et al., 2021), due in part, to an increase in internet usage and information retrieval technologies (Webb et al., 2001) of student data.

Machine learning techniques have mainly been used in two areas of student modeling research. First, to induce a student model from many student behaviors, and second to create a bug library of student models. For instance, Baker (2007) constructed a machine learning model that was able to detect when a student was off-task. Baker et al. (2012) detected emotions of students based on log data of actions with an Algebra ITS system, rather than with physical sensors that other affect detection systems may use. Finally, Baker et al. (2006) used data mining techniques to detect students who were trying to game the system by getting to a bottom-out hint rather than engaging in deep learning; students were then given supplementary exercises based on the ones they attempted to bypass. Gobert et al. (2015) used machine learning on students' logfiles within a science inquiry assessment and learning environment to detect students' disengagement from learning; Gobert et al. (2012, 2013) also used machine-learning for assessment of students' inquiry competencies.

The move towards real time performance assessment & real time scaffolding of inquiry competencies

As addressed earlier in the entry, many ITSs have been designed for well-defined domains. By this, we mean, domains that have one correct answer, such as ITSs for math problems (Corbett and Anderson, 1995; Feng et al., 2009; Gertner and van Lehn, 2000) like the addition of $2 + 3$, or double-digit addition, etc. For domains in which there is one correct answer, the assessment of students' knowledge and skills is fairly straight-forward, and computational techniques including machine-learning, described above, are not typically necessary. In these cases, rather, knowledge-engineering (cf. Koedinger and MacLaren, 2002) is used for both assessing students and scaffolding them. Briefly, in knowledge engineering, a domain expert constructs by hand a cognitive model to capture what it means to demonstrate a sub-component based on the constructs of the domain and/or cognitive task analyses (Ericsson and Simon, 1980), then techniques such as model tracing are used to compare students' knowledge and skills to that of an expert, and intervene when the system detects a difference between the two. Additionally, there are science domains, such as Physics and Chemistry, which include mathematics in their underlying formulas, equations, etc., and they too can use knowledge-engineering for these mathematical aspects of the domain. Some examples here are VanLehn's et al. (2005) Physics Tutoring system for college level Physics problems, which helps students by giving them assistance as they set up free-body diagrams, write equations, and solve them, and Walsh et al.'s (2002) intelligent tutoring system for balancing chemical equations.

Science inquiry, which is the means by which a learner engages in a series of tasks related to forming a testable hypothesis, conducting an experiment to test a hypothesis, analyzing a resulting data, and then communicating findings, is an ill-defined domain (Kuhn, 2005). It is ill-defined because there are many ways in which students can complete a task both productively as well as unproductively. Thus, both scaffolding and the assessment of students' competencies that is required in order to scaffold students (as is the goal of ITSs), is much more complex. Described next in this entry is Inq-ITS Inquiry-Intelligent Tutoring System (inqits.com; Gobert et al., 2013) in order to exemplify an ITS for science inquiry, and how machine learning is used in an ITS of this type. We also use Inq-ITS to describe the core components described above (where applicable for Inq-ITS). Lastly, we provide an overview of Inq-ITS scaffolds and an overview of some results of our scaffolding research.

Inq-ITS is a computer-based system, i.e., an ITS, that provides both real time assessment and scaffolding of science inquiry practices as described in national and international science frameworks, including the Next Generation Science Standards (NGSS, 2013). In brief, using simulations and a series of inquiry tools, widgets, etc., students formulate hypotheses and questions, test them, interpret their data with graphs and other mathematical means, warrant their claims with evidence, and communicate their findings. As students conduct their investigations, the work products they create and processes they use by conducting their investigations are automatically assessed using integrated machine-learning as well as knowledge-engineering, where relevant (Gobert et al., 2013, 2016, 2017, 2019; Mislevy et al., 2020). In addition, Inq-ITS supports teachers' real time assessment and instruction of inquiry practices (NGSS, 2013) using real time reports and actionable alerts via a dashboard called Inq-Blotter (Dickler et al., 2021; Gobert, 2019; Gobert et al., 2019; Gobert and Sao Pedro, 2016; Sao Pedro, 2015, 2016), though these are not the focus of the present chapter (see Dickler et al., 2021 for details on Inq-Blotter).

Inq-ITS was explicitly designed to prioritize the assessment and scaffolding of inquiry rather than the learning of science, which many other curriculum-focused inquiry systems emphasize (cf., Linn and Hsi, 2000). Inq-ITS was informed by the assessment triangle, which includes cognition, observations, and interpretation (Pellegrino et al., 2001), and by Evidence-Centered Design (Mislevy et al., 2020) in which the system elicits and collects evidence of students' proficiencies at inquiry practices (Gobert and Sao Pedro, 2017), i.e., this is performance assessment. In brief Evidence-Centered Design (ECD; Mislevy et al., 2009, 2020) is a design framework that helps specify all the key elements of an assessment system and an intelligent tutoring system, including the domain model, the interface model, the student model, and the tutoring model. ECD also specifies the fine-grained details and the computational processes (critical to interpretation of student data) that are to be carried out in the assessment system in order to generate fine-grained, rigorous assessment data on students' competencies, and in turn, scaffolding. This approach is different from the assessment of rote knowledge of facts or formulas, which can be assessed via multiple choice items. Rather, performance assessment of science inquiry is done as students engage in rich, authentic inquiry tasks with simulations so that the system can act *intelligently* to support students' learning.

Inq-ITS builds on the inquiry and assessment research of others (some of which was reviewed earlier) and forges new ground for inquiry assessment and scaffolding of science with its application of computational analytics including educational data mining, knowledge-engineering, and natural language processing (Gobert et al., 2013, 2016, 2017, 2019). The machine-learned algorithms allow the system to better capture what kinds of difficulties students have with inquiry, and then based on students' difficulties, Rex, a cartoon dinosaur that acts as a virtual pedagogical agent, jumps in to help the student in real time (See Fig. 1 below). These algorithms were built on diverse samples and tested for generalizability, which ensures equity with respect to the new students who later use these systems (Sao Pedro et al., 2013b).

To illustrate how the system works, as well as how the architectural components of an ITS are represented, a small vignette is presented. An eighth grade teacher, Mrs. Donahue, is having her class conduct an inquiry with Inq-ITS' States of Matter Physical Science virtual lab (See Fig. 1, left). In this lab, students determine the effects of the independent variables (e.g., level of heat, amount of substance) on the dependent variables (e.g., time to melt, temperature when melted) by forming a hypothesis, collecting data to test their hypothesis using the simulation, analyzing their data, and communicating their findings.

At a high level, students engage in virtual inquiry with our widgets and a domain-based simulation of a science phenomenon; this includes, forming a question/hypothesis, collecting data with a simulation, interpreting data, warranting claims with data, using mathematics to develop deeper understandings of the phenomena under study and communicating findings about the investigation (Gobert et al., 2012, 2013, 2016, 2019). The simulation environment represents the *domain model* of the science phenomena under investigation, while the simulations, widgets and clickable options presented to students in Inq-ITS demonstrate the *user-interface model*. The Inq-ITS activities leverage the logging infrastructure to store all students' interactions (logfiles) at a fine-grained level, including students' interactions with widgets, representational tools, and simulations, and timestamps for those interactions (Mislevy et al., 2020; Gobert et al., 2012; Sao Pedro et al., 2013a); these are used to construct a student model of the students' competencies across the full range of inquiry practices, which informs the tutoring model.

Fig. 1 As students conduct inquiry with Inq-ITS, their inquiry is automatically assessed by underlying algorithms. Rex reacts in real time to support students' learning in the moment. Real time reports and alerts are also generated in real time to support teachers' assessment and instructional needs.

Having a logging infrastructure that collects all students' interactions provides many benefits for intelligent tutoring systems. In terms of *research*, the system can effortlessly and accurately monitor and record every student action; this is important for testing the efficacy of scaffolds in an ITS. Regarding *assessment*, by seamlessly doing assessment in real time and at a fine-grained level, it can assess and remediate students' specific inquiry difficulties in the rich contexts in which they are learned (Mislevy et al., 2003). In terms of *instruction*, it can seamlessly integrate assessment with instruction so additional class time is not needed; that is, the tutor Rex can respond to individual students in real-time as they conduct inquiry, when it is most beneficial for learning; and it can provide formative data and actionable alerts to teachers about his/her students easily and automatically via our dashboard Inq-Blotter (Dickler et al., 2021; Gobert, 2019; Gobert et al., 2019; Gobert and Sao Pedro, 2016; Sao Pedro, 2015, 2016). With regard to *scalability*, because these materials are web-based, virtually any teacher with access to the web can use the ITS.

Furthermore, there are great advantages for analyzing rich logfiles of students' learning using machine-learning, as is done in Inq-ITS. These are often referred to as the 4Vs (Laney, 2001), namely: the large volume of log data, the velocity at which it is generated, the veracity in fine-grained logfiles, and the variability in students' logfiles since there are many ways in which inquiry can be done both productively and unproductively. However, theory is needed to both distill and aggregate data (Quellmalz et al., 2012), and to design categories a priori so that results are pedagogically meaningful (Gobert et al., 2013). In Inq-ITS, algorithms are used to derive rules based on cognitive task analysis (Ericsson and Simon, 1980) of student interaction data and/or human-classified labels of those data that were developed from the national inquiry frameworks (NRC, 1996; NGSS, 2013) as well as data (Gobert and Sao Pedro, 2017) and literature on students' difficulties with conducting inquiry (cf. Kuhn, 2005). Then, machine learning is leveraged to derive algorithms for process-oriented practices that can be exhibited in several different ways, e.g., collecting data (Sao Pedro et al., 2013a,b). The results are aggregated into performance indicators that provide evidence of students' proficiencies for each inquiry practice and their respective sub-skills, and the system is instrumented to jump in to provide real time feedback to students when the system detects that students are struggling on the inquiry competencies of interest.

Inq-ITS delivers scaffolds to students in text format via the pedagogical agent, Rex (see Fig. 1). This proactive scaffolding approach helps to support students in their inquiry processes (Schauble, 1990; deJong, 2006) by preventing students from engaging in unproductive behaviors (Buckley et al., 2006; Sao Pedro, 2013). This proactive approach is also important because students may not be aware that they need help (Aleven and Koedinger, 2000; Aleven et al., 2004).

Scaffolds in Inq-ITS

In Inq-ITS, the primary scaffolding strategies used by the pedagogical agent are explanations provided by Rex (see Fig. 1). Such scaffolding is based on principles from cognitive psychology (McKendree, 1990), and this approach to scaffolding has been shown to benefit learning in other domains (Beck and Mostow, 2008). The scaffolds involve multiple steps or levels (cf., Wood and Wood, 1999), similar to Cognitive Tutors (Anderson et al., 1995). In Inq-ITS, scaffolds are triggered by our assessment algorithms (cf., Gobert et al., 2013, 2016; Sao Pedro, 2013) when the systems detects students' difficulties with inquiry. An example set of the progression of scaffolds that is triggered when a student is not designing controlled experiments, a key skill in science inquiry (Kuhn, 2005), is presented below.

1. Orienting scaffolds are designed to orient the student to the current task within the inquiry cycle since students have difficulties monitoring their progress (de Jong, 2006). For this, Rex may state that in the experiment phase, data should be collected to help support or refute a stated hypothesis.
2. Conceptual scaffolds are designed to provide a high-level hint to the student, e.g., if a student has collected confounded trials (Sao Pedro, 2013), Rex may ask, "How will you know about the effects of x on y, given your trials?"
3. Procedural scaffolds are designed to provide information about the procedure to use on the current task, e.g., Rex may instruct the student to "construct a controlled trial, *relative* to your last trial run." Explicitly teaching this strategy has been shown to be effective (Klahr and Nigam, 2004; Sao Pedro et al., 2009, 2010).
4. Instrumental scaffolds are designed to tell the student exactly what to do on the current task, i.e., a "bottom-out hint" (cf. Aleven and Koedinger, 2000). For example, Rex may instruct the student to "conduct a set of trials in which you change only one variable while keeping the others the same."

Using scaffolds like these, Gobert and her team have demonstrated the effectiveness of our assessment and scaffolding approach at the middle school level for several NGSS practices, including forming questions, planning and carrying out investigations, analyzing and interpreting data, and warranting claims in which scaffolding helped students both acquire and transfer these practices to new Inq-ITS topics over long periods of time, tested up to 170 days (Li et al., 2018, 2019a,b; Gobert et al., 2018; Moussavi et al., 2016; Moussavi, 2018; Sao Pedro et al., 2013a,c).

Conclusions

In summary, the last half century has seen dramatic changes in ITS developments and innovations, enabling ITSs with new capacities, which greatly impacts learning. Important among them is fine-grained student modeling. This, in turn, allows for fine-grained assessment, diagnosis, and personalized tutoring.

This entry also highlights how another innovation, namely machine learning, can be used in an ITS, specifically Inq-ITS. Machine learning in Inq-ITS is used to elicit students' inquiry performances while they engage in inquiry, assess their competencies in real time, and trigger scaffolding to them in real time in order to help them learn the science competencies expected by national frameworks (NGSS, 2013). Furthermore, well-designed, targeted scaffolds that are based on fine-grained, rigorous assessment of students' competencies *can* lead to robust student learning even for ill-defined domains such as inquiry. In sum, this approach to assessment and scaffolding can and should inform the design of assessment and intelligent tutoring systems so that systems are instrumented to assess and support *all* students, regardless of zip code, ELL status, etc. Furthermore, it is imperative that technological resources be leveraged so that ITSs are scalable to provide learning benefits far beyond what an individual teacher can provide.

Introduction

The primary goal of educational assessment is to infer attributes about a learner from observation of their performance on a given activity. Historically, this has been accomplished by presenting students with a defined set of items, usually framed as questions, to which they respond. The items are then scored based on the correctness of the responses and aggregated into a score meant to tell us about what the learner knows and can do. However, we now live in a digital world where students engage in a variety of rich activities from which we can gather detailed data. This ability to capture and analyze information from students' daily learning activity should fundamentally change how we think about assessment (DiCerbo and Behrens, 2014). It opens up the kinds of activities that can be considered as assessments, the kinds of evidence that might emerge from those activities, the ways we score that evidence, and the way we aggregate it. Ultimately, it could change the kinds of attributes about which we are able to make valid, reliable, and fair inferences.

Simulations and games are two types of digital activity that have the potential to be used for assessment purposes. Educational simulations are representations of systems or elements of systems that students interact with for learning purposes. Even prior to digital education, simulations were used, particularly in medical and business education, to allow learners to practice skills and explore concepts with reduced risk, in this case to actual patients or businesses, respectively. With the advent of the digital world, simulations have expanded both in their potential capabilities and educational usage. Cell simulations in biology and simulations of data packets moving through computer networks, for example, allow learners to see otherwise unobservable processes. A variety of science simulations allow learners to ask "what if" questions and try things that could be dangerous or impossible in the real world. A review of 59 studies examining the impact of simulations on learning indicated that, overall, simulations have a beneficial effect on achievement over instructional practices in which there were no simulations (D'Angelo et al., 2014).

Educational games can be hard to differentiate from simulations. Generally they have a better defined goal state and rewards system (D'Angelo et al., 2014) and more defined rules (Salen and Zimmerman, 2003) than simulations. Games are seen as attractive potential learning tools because they are so engaging. Teachers and parents wish their learners were as engaged with learning material as they are with entertainment games. As with simulations, many teachers employed games prior to the digital era, but computing technology has brought a new batch of games from the early days of *The Oregon Trail*, which is a series of educational computer games originally produced in 1971, to games that provide reinforcement for practice of basic skills to games that encourage deep investigation of concepts. Reviews of games as learning tools consistently show a positive impact of games on learning but not on motivation (e.g., Clark et al., 2016; Wouters et al., 2013).

However, in addition to being good learning tools, simulations and games lend themselves well to assessment. As Gee (2010), a pioneer in games for learning, pointed out "if players finish the game Halo, there is no question that they are experts in playing Halo, we don't need to give them a separate test to find out if they are good." In the early 2000s, this statement prompted many in the assessment community to wonder, whether a game that required the use of target knowledge and skills more aligned with standards than Halo could become an educational assessment of academic skill. In addition, the increase in our ability to store, capture, and extract digital data caused the community to begin to explore using process data, or the record of the interactions of learners with the system, as evidence of the process of problem solving, providing information beyond a final answer's correctness to increase our understanding of what learners know and can do.

Assessment in the digital ocean

Historically, in order to observe and evaluate learner behavior at scale, for example, in order to make judgments for certification of proficiency for professionals, it was necessary to employ fixed-time, forced-response tasks that were distal proxies of day-to-day activities. Specific data needed to be collected in a specific amount of time, from a large group of people, and so efficiently implemented, forced tasks were required.

In contrast, in the educational practice of teachers, the assessment model has been much more fluid: interactions occur repeatedly over time, the context of activity is consistent with current goals, observations and performance are made and characterized formally and informally, and the subsequent activities of instruction are introduced in light of previous performance. In such contexts, assessment becomes a natural ubiquitous and unobtrusive (Behrens et al., 2007) side effect in the natural environment or what Shute calls *stealth assessment* (Shute et al., 2009).

The first paradigm benefits from formalization of rules of evidence, standardization of experience (allowing for comparability), collection of data, and data analytics while suffering from decontextualized tasks. It also tends to emphasize one correct answer and one right path to get there. The second paradigm benefits from contextualized and “authentic” tasks while suffering from informal data collection, rules of evidence and analytics, and difficulty with comparability and communication outside a specific classroom. The emerging universality of digital tasks and contexts provides the opportunity to unify the strengths of each of these approaches. As the digital instrumentation needed for educational assessment increasingly becomes part of our natural educational activity, the need for intrusive assessment practices that conflict with learning activities diminishes.

This vision, described in Shute et al. (2016), does not involve administering assessments more frequently (e.g., each week, each day) but, rather, continually collecting data as students interact with digital environments. It relies on data that are unobtrusively gathered while students are playing/learning in carefully designed environments that then allow inferences to be made about relevant competencies. As the various data streams coalesce, we obtain more evidence about what students know and can do across multiple contexts. The vision of assessment in technology-rich environments involves high-quality, ongoing, unobtrusive assessments that can be aggregated to inform a student’s evolving competency levels (at various grain sizes) and also aggregated across students to inform higher-level decisions (e.g., from student to class to school to district to state to country).

However, even without arriving at this comprehensive vision of ongoing assessment, there are other levels of digital assessment implementation that take advantage of the possibilities the digital world has to offer. DiCerbo and Behrens (2012) layout a categorization scheme for thinking about these possibilities. Level one merely replicates traditional assessment activities in a digital environment. Level two involves new assessment activities that allow new types of performances and new types of information. This includes, for example, complex simulation tasks that require integration of multiple skills and collect data about the process learners use to solve the problem. Level three involves embedding assessment in the learning environment, for example, as a game that is threaded through semester-long courseware that serves as both a learning tool and a means to understand what learners know and can do. Level four is the vision described above of a system that integrates inputs from multiple digital activities over time to build an understanding of what learners know and can do. Even at level two, there is potential progress being made toward not just technology-enhanced assessment, but assessment-enhanced technology.

Process data

One objection to traditional, standardized measures of assessment is that they produce a single, binary data point from each question: correctness or incorrectness of the final answer. This does not help us understand how a learner arrived at a particular response, which can be key in remediation (and also key in identifying whether there are potentially other correct answers). Digital environments allow us to capture many features of a learner’s performance on an activity, for example time, sequence of activity, and counts of actions. For example, the game *SimCityEDU* is designed to assess systems thinking, particularly the ability to understand how actions in a system have multiple, interrelated effects. Players are dropped into a city that is already built and is experiencing problems, where they are asked to diagnose and fix the issues. It turns out that there is significant air pollution in the city, and that coal plants are causing a lot of it, however, coal plants also provide power to the city. By observing a sequence of actions, whether the player installs alternative forms of energy prior to bulldozing the coal plants or not, provides us evidence about whether the learner understands that the coal plants have multiple effects on the city, as opposed to just the single effect of air pollution. Gathering multiple observations of similar choices, allows us to build models of players’ levels of systems thinking (DiCerbo et al., 2015).

This ability to capture log file data opens the possibilities of providing insight into a learner’s process of problem solving, not just their final answer. This insight can then help point to particular areas where a learner’s solution might differ from the “prescribed” solution. Over time, and thousands or tens of thousands of users, we will be able to identify even less common solution paths in digital experiences, often with the help of exploratory data analysis (Behrens et al., 2012; DiCerbo et al., 2015). In the *SimCityEDU* game, over time it became apparent that a small percentage of players “solved” the air pollution problem by bulldozing the entire city. Rather than simply tagging these as “wrong,” it was instructive instead to explore why learners follow a particular path. Interviews with learners revealed that bulldozing things is fun, that’s why players chose it as a solution, and we should not infer anything about the systems thinking ability, positively or negatively, for those who bulldozed the whole city.

In the classroom, conversation around why a learner took a particular path of action can open up a rich dialog about how a learner has framed a problem and selected a solution option. Clearly, this kind of discussion is beyond the means of our digital capabilities; it is the domain of a capable teacher. Ideally, the digital experience provides a gateway or launching point for these conversations that go far beyond discussions of correctness. Teachers have been exhorting students to “show your work” for decades and the digital world can help make that a default for all students, and help uncover patterns in the process. However, the collection and manipulation (both technically and statistically) of process data requires new infrastructure and new ways of thinking (Behrens and DiCerbo, 2014). As we will see, most projects attempting to make use of this new data have not been implemented at scale.

Simulation-based assessment examples

Given that a goal of education is to help learners apply knowledge and skills in the real world, simulations are attractive as assessment tools because they can place students in scenarios that require this application, even if they don't make use of all of the potential of process data. There are a number of simulation-based assessment that ask students to engage with a simulation but then answer traditional question types, which provide the evidence for scoring. For example, the state of Minnesota has released a science assessment item based on water bottle rockets from their end of year summative state science assessment (http://minnesota.pearsonaccessnext.com/resources/item-samplers/science/item-samplers/grade8/Grade8_Science_MCA_ItemSamplerScript.pdf).

Students select what size bottle to use, how much water to put in, and the pressure of the air to be pumped in. They click Run button on the screen and can observe the launch of the rocket and its return to earth. Students then answer a series of questions about the simulation in traditional item types. For example, they are asked to run multiple trials with different amounts of water and then asked a multiple choice question about what happens to the height of the rocket as the volume of water increases (decreases, stays the same, increases then decreases, or decreases then increases). There are different item types available, including one that asks students to drag and drop arrows to indicate the direction of forces, but there is no data captured about students' interactions with the bottle rocket simulator. The items therefore do allow students to interact with more real world examples and carry out experiments, but the evidence available is still limited to the correctness of their response.

In the formative space, in which assessment is to inform instruction rather than evaluate it, *SimScientists* (simscientists.org) has complex simulations for students to interact with, and has students answer questions in more traditional item types, which are then aggregated using Bayesian Networks to estimate probabilities of mastery of science-based standards (Quellmalz et al., 2020). *Inq-ITS* (inqits.com), a commercially available simulation and assessment tool, has created virtual labs that walk students through the process of developing a hypothesis, changing variables, analyzing the results, making a claim, and choosing evidence for that claim, all through multiple choice and other selection based items. They have broken down the scientific inquiry process into sufficiently granular steps that they can provide feedback about the steps students take when designing an experiment without providing a wide open environment that makes it difficult to manage data and score responses. *Inq-ITS* also lets students explain their findings in more open-ended writing and scores the open-ended responses with Natural Language Processing-based Artificial Intelligence algorithms. These scores are then aggregated and reported as measures of proficiency on science inquiry skills like collecting data and explaining findings to teachers and students.

Attempts to use process data as evidence in more open simulations have remained in the realm of research projects. The *PhET Interactive Simulations* are a well-known set of science simulations used widely for learning. Since creating data hooks in their HTML5, there have been a number of research projects attempting to model the process data from them. For example, LaMar et al. (2017) attempted to create detectors of students' strategy in a PhET chemistry simulation on solutes using process data. They were able to use the behaviors of increasing or decreasing solute across trials to infer students' goals and strategy.

There have also been attempts to combine process data with more traditional data. For example, Choi et al. (2019), a research team in partnership with the state of Minnesota, developed a simulation to assess engineering design processes around developing and optimizing solutions. Students were asked to build a submarine to meet certain specifications (e.g., depth it could go, speed, and capabilities), test it, and revise based on results. Information about student actions was gathered, including the number and kinds of parts used, pattern of testing, and responses to failed tests. In addition students were asked forced-choice questions about relevance of parts to solving the missions and causes of failure. This information was combined via measurement models to produce assessments of engineering design skill.

However, using process data as evidence is currently difficult to move into production for a variety of reasons, including: (a) it is labor intensive to identify the potential evidence pieces that will be aggregated, and to write code to extract those evidence pieces from large activity log files, (b) the technical requirements to capture the amount of data required over unstable school internet connections are substantial, and (c) there are significant infrastructure changes needed to store vast amounts of unstructured log file data when existing systems are designed to capture highly structured response data.

Game-based assessment examples

The above-mentioned challenges exist for game-based assessments too, along with the challenge of adding creating an engaging game along with an assessment. There are three potential approaches to game-based assessment: (a) creating a game-based assessment from scratch, (b) modifying an existing game, and (c) using an existing game as-is. However, in each case, those who have built them generally agree it is essential to start the process with a model of the skills and knowledge to be assessed, usually in the form of some kind of taxonomy or learning progression.

Mars Generation One: Argubot Academy is an example of a made-from-scratch game-based assessment. Designed by GlassLab in the mid-2010s, this game place players on the first colony on Mars, where there are many decisions to be made about how to run the colony, and decisions are made through robot battles. The game is meant to assess argumentation, and design began by identifying a learning progression describing how learners move from novice to expert levels in different areas of argumentation, such as constructing arguments and evaluating others' arguments. Players establish claims they want to make, for example, whether the primary source of food should be insect, plant, or mammal. They then move through the environment collecting evidence to support their claims. They build robots by matching claims to evidence. Robot battles consist of having built a robot with strong claim-evidence

pairs and finding weaknesses in the opposing robots' claim and supporting evidence. Pieces of evidence for inferences included: which pieces of evidence were collected, how claims and evidence were linked, and ability to identify weaknesses in opposing robots.

SimCityEDU was an effort by the same group who created *Mars Generation One*. In this case, EA, the game company, allowed use of *SimCity*, an open-ended city building game for the creation of the game-based assessment, so this was an example of modding an existing game. The player controls where to place infrastructure like roads and power plants, landmarks, and public services such as schools, parks, hospitals and fire stations. The player also determines the tax rate, the budget, and social policy. The city is populated by "Sims", simulated persons, who live in the city created by the player. The *SimCityEDU* team sought to use this structure to assess students' systems thinking, or understanding how parts of a system are interrelated and how changes in one part will impact changes in other parts. In order to constrain the game sufficiently to ensure it was possible to observe evidence related to systems thinking, the developers created scenarios where cities were already built and players had to troubleshoot problems in the city. The scenario of the excess air pollution was described above. Creating these scenarios involved significant development work to modify the existing game but it did allow access to a popular game made by a large team of designers, already known to be engaging. In the end, however, there were very few evidence pieces that actually provided information about learners' systems thinking skills.

A final option is to simply add in data hooks and an assessment model to an existing game, but not introduce any new game play. This was done with the popular game *Plants vs. Zombies 2* (Shute et al., 2015). In *Plants vs. Zombies 2*, players must plant a variety of special plants on their lawn to prevent zombies from reaching their house. Each of these plants has different attributes. For example, some plants (offensive ones) attack zombies directly, while other plants (defensive ones) slow down zombies to give the player more time to attack the zombies. A few plants generate "sun," an in-game resource needed to purchase more plants. The challenge of the game comes from determining which plants to use and where to place them in order to defeat all zombies in each level of the game. The authors identified four facets of problem solving: (a) analyzing givens and constraints, (b) planning a solution pathway, (c) using tools and resources effectively, and (d) monitoring and evaluating progress and then identified actions in the game that aligned to these facets. These actions were aggregated to create problem solving scores for players.

One of the most researched game-based assessments is *Physics Playground* (originally called Newton's playground; Shute et al., 2013). Based on the puzzle video game *Crayon Physics*, the game requires the player to guide a green ball to a red balloon by drawing/creating simple machines (which are called agents of force and motion in the game) with the mouse. The objects come to life once the object is drawn. Everything obeys the basic rules of physics relating to gravity and Newton's three laws of motion. There are more than 70 levels to the game and players win trophies for completing them. Initial studies used these trophies as evidence of proficiency while later studies developed models with multiple in-game actions providing evidence about players understanding of qualitative physics.

Through these descriptions, it should be clear that there is a tension between the openness of game play and the need to observe specific behaviors in assessment. Some of the attractiveness of games comes from player choice and agency, and that can be diminished to the point of losing the fun when the design forces players into paths to observe certain behaviors. However, without this forcing function, the assessment data are often lacking and there is not enough evidence to make reliable estimates. These challenges face game-based assessment on top of all of the technical challenges described for simulations.

Validity, reliability, and fairness

To quote Messick (1994), "such basic assessment issues as validity, reliability, comparability, and fairness need to be uniformly addressed for all assessments because they are not just measurement principles, they are social values that have meaning and force outside of measurement wherever evaluative judgments and decisions are made" (p. 13). These concerns do not go away in the new digital assessment world. The validity and reliability of the assessment data affect the accuracy of the student diagnosis, and the diagnosis informs instructional support. If the first part of the chain is weak, the rest (i.e., diagnostic accuracy and effective instructional support) would consequently be compromised (Shute and Zapata-Rivera, 2010). However, many of the techniques used for measuring the psychometric properties of assessment were developed in the context of standardized assessment, consisting of discrete items specifically designed to assess a single construct, scored as correct or incorrect. Much of the evidence gathered from simulation- and game-based assessments (e.g., time spent and sequence of events) is not scored as correct/incorrect and often relates to multiple constructs. In addition, there is often variability even in what activity is presented to learners. In game-based assessment, for example, players' previous choices and actions, and the immediate feedback received, will result in differing activity sequences from player to player and from play occasion to play occasion for the same player (Kim and Shute, 2015). As a result of these differences, in some cases the models and techniques for estimating particular types of reliability and validity evidence will need revision to be applicable for new types of activity and data.

A review of validity and reliability evidence for ongoing and stealth assessments can be found in DiCerbo et al. (2017). Regarding reliability, both inter-rater and internal consistency measures can be employed with traditional methods (with some modification allowing for correlation among constructs and errors). However, our ideas of test-retest validity often fall apart because they rely on the construct remaining stable over time. In the new digital environments from which we collect technology, people are often learning as they engage. Similarly, common methods employed in generalizability theory studies cannot be applied because not all students complete all activities and many pieces of evidence are related to multiple constructs. In these cases, more work is

required of the field to go back to the foundations of what Generalizability Theory (Brennan, 1992) addresses in order to develop methods that apply to new conceptualizations of assessment.

Similarly, examining the five types of validity evidence in relation to simulation- and game-based assessment presents a mix of results and demand for new methods. Evidence based on content can be evaluated with known tools and efforts to do so suggest assessments in new digital environments are at particular risk for introducing construct-irrelevant variance, such as game play experience, into estimates of knowledge and skill. Evidence based on response processes and internal structure can be gathered through usual methods. Evidence based on relations to other variables presents a demand for adjustment to traditional rules of thumb. Scores from simulations and games can clearly be correlated to other measures of the same construct. However, it is not clear what constitutes acceptable levels of correlation. If complex performances are measuring constructs at a deeper level than traditional measures, through the inclusion of process data, for example, very high correlations would not be expected between the digital and traditional measures. It is not clear that the existing measure should be the “gold standard” if the more complex performance is closer to the real-world performance we want to make inferences about. However, traditional psychometricians would argue that if correlations are not that high, then the measures are assessing different constructs. In some cases, Cohen’s (1992) definition of a large correlation as 0.50 or above is used as a cutoff for whether a test demonstrates convergent validity. In other cases, a significant, non-zero correlation is viewed as acceptable evidence. The field has not had these discussions as a whole to determine what counts as compelling evidence. Finally, as with traditional assessments, evidence based on consequences of use of simulation- and game-based assessments is sparse and lacking.

Challenges to the field

To be accomplished appropriately, development of simulation- and game-based assessment involves time and money. Here are just a few key tasks required to make a learning game with assessment baked in:

- Understanding how learners progress in the content area. Is there existing research about stages a student goes through when learning a concept? Are there common misconceptions? Research on learning progressions often aligns synergistically to game levels. However, this research must be synthesized and translated into game developers’ language.
- Aligning a core loop of game play to the learning loop. The core loop of game play is the repeating series of activities that drive game play forward. In an educational game, that game play loop should be aligned to the skills to be taught and assessed. For example, in *Mars Generation One: Argubot Academy* a key loop of activity is: identifying evidence, linking evidence to claims, and then identifying problems in an opposing person’s argument. Game play was designed to follow that same loop as players moved through the environment on Mars, interacting with characters to gather evidence, built robots for battles by making claim and evidence pairs, and then engaging in robot battles by putting their claims and evidence against others’.
- Creating evidence models. It is necessary to determine what choices in the game tell us about a players’ knowledge and skill. These choices must be designed into the game so the options available differentiate between people who are proficient in a skill of interest and those who are not. In other words, someone who is proficient is likely to make one choice and someone who is not is more likely to make the other. These choices become pieces of evidence. However, the complexity of game play often means that there may be non-hypothesized activity patterns that also help differentiate skill levels. Use of exploratory data analysis (e.g., Behrens et al., 2012; DiCerbo et al., 2015a,b) and machine learning (e.g., Gobert et al., 2013) or combination of both (e.g., see Rosé et al., 2019) can help uncover these. However, all of this work takes time, expertise, and skill.

It takes many iterations of building and testing to get both the game play and the evidence models right. All of the work requires experts in content, assessment, and game design to work in close collaboration. The amount of time and budget it currently takes to make a quality game does not match up to the budgets and timelines of curriculum development at scale. There have been countless interesting, quality games developed that cover a small portion of curriculum content. These individual games often find homes with passionate teachers who adopt them and work them into their classroom practice. However, this is not deployment at scale. Teams have tried to create minigames (a very short game), built game templates for reuse, or rely on a single game mechanic. However, in order to get to scale, we likely need both new business models for partnerships and new processes and procedures for development. Perhaps in the future artificial technology, for example, can do more of the evidence identification work. In current reality, there is a large gap between what we can build in an Research & Development space and what we can build at scale.

Introduction	478
Terminology issues	478
What are the interpersonal and intrapersonal skills?	479
Findings related to interpersonal and intrapersonal skills	480
Interpersonal and intrapersonal skills predict academic outcomes	480
Interpersonal and intrapersonal skills predict non-academic outcomes	481
Unlike the case with cognitive abilities, there are multiple, distinct interpersonal and intrapersonal skills	482
Interpersonal and intrapersonal skills appear to change over time but not in exactly the same way cognitive skills do	482
Interpersonal and intrapersonal skills can be improved	483
There are some subgroup differences in interpersonal and intrapersonal skills, but they are smaller than and different from cognitive skill differences	483
Others'-assessments of soft skills are more predictive of outcomes than self-assessments, but the two provide complementary, not duplicative information	484
Noncognitive and cognitive skills are distinct but they overlap and are difficult to disentangle	485
Uses for interpersonal and intrapersonal skills assessments	485
Approaches for assessing interpersonal and intrapersonal skills	486
Ratings	486
Multidimensional forced-choice (ranking)	487
Situational judgment test (SJT)	487
Performance tasks	488
Conclusions	488
Acknowledgment	488

Glossary

d A statistic indicating a standardized difference between groups, that is, a mean difference between groups expressed in a standard deviation metric, that is as a proportion of a standard deviation

r A correlation coefficient indicating level of association between two variables on a scale from -1.0 (perfect negative correlation) through 0 (no association at all) to $+1.0$ (perfect positive correlation)

Soft skills Social, emotional, and self-management skills (including traits, attitudes, values, beliefs). Mostly synonymous with interpersonal and intrapersonal skills. Soft indicates a distinction with hard skills, which typically refer to mathematics, language, and technical skills

Interpersonal and Intrapersonal Skills See *Soft Skills*

Multidimensional forced-choice A testing item type in which a respondent is asked to select (or rank) one of two (or more) statements with respect to which statement they agree with more, or prefer, or believe better characterizes them. The statements reflect different dimensions, such as diligence, cooperativeness, curiosity, and sociability

Situational Judgment Test (SJT) An item type in which a situation is presented (as text, audio, or video) and respondents are asked to indicate their response to the situation. The response typically involves either ranking or rating options with respect to how one might best or how one might typically respond to the situation

Likert scale An item type used to measure personality, attitudes, values, beliefs, feelings, and behaviors. A statement is presented followed by a rating scale that asks the respondent to indicate a level of agreement, endorsement, or frequency, on a 5-point scale (i.e., 5 response categories, such as "strongly disagree," "disagree," "neither agree nor disagree," "agree," and "strongly agree"). Variations on the Likert scale have come to include fewer or more response categories. Named after its originator, Rensis Likert, the developer of the method (Likert, 1932)

Subgroup Typically, in the context of testing, a group identified primarily through self-report, based on gender, race, ethnicity, age, country of origin, socio-economic status, or other demographic characteristics

Outcomes, academic Variables such as grades, graduation, disciplinary infractions, time to degree, teacher evaluations, and participation in school activities, that serve as measures of success in school

Performance tests Measures based on individual (or group) performance on a task (e.g., problem solving, decision-making), in contrast to self-ratings or others'- (teacher, guardian) ratings

Big Five Personality Model (or Five Factor Model) A model to characterize the dimensions of personality based on factor analyses of item responses. The model was identified following analyses of personality item responses in many, diverse settings, across diverse sets of items. The model has served as a standardization in terminology to enable meta-analyses and to evaluate proposals for new personality constructs

Meta-analysis A quantitative synthesis of primary studies that include common variables or variables that can be classified that way. The technique is typically used to estimate correlations or treatment effects by aggregating results from primary study samples weighted by size

Factor analysis A statistical technique for analyzing a matrix (e.g., a correlation matrix of test scores or of item responses), to reduce the number of dimensions needed to summarize or characterize the matrix. It is used in individual differences research to identify the main factors needed to account for the pattern of test score or item response correlations

Introduction

Schools teach skills and assess them to monitor student progress and to award scholarships and favorable admissions decisions. But what is a skill? In the context of education and human capital theory, skills, broadly speaking, refer to the knowledge and capabilities students acquire that prepare them for future learning and successful performance in the workplace. Skills have typically been thought of as a kind of knowledge of how to do something—drive a car, solve a puzzle, program a computer. But there is a growing appreciation for a more expansive view of skill that encompasses interpersonal and intrapersonal aspects. Working hard, being curious, and working well with others can also be thought of as skills under this broader, contemporary perspective.

Two important distinctions are often made about skills. One is between general skills, such as literacy and numeracy, applicable to a broad variety of domains, and domain-specific skills, such as horse-race handicapping or network programming, applicable to a narrower set of tasks or circumstances. The other distinction is between *hard* and *soft* skills. Hard skills refer to those recognized and assessed as part of the formal academic curriculum, for example, reading, writing, mathematics, and science. Soft skills refer to those not taught as part of the formal curriculum, but that are acquired as a part of school anyway. These include being prompt and reliable in attendance and homework, listening to the teacher, being curious and acquiring a love of learning, being in control of one's emotions, and being able to communicate effectively with teachers and classmates. These skills have not always been considered skills at all and have historically been downplayed if not overlooked entirely in assessment, particularly large-scale school assessments. For example, state accountability assessments, licensure examinations, and international student comparative surveys such as the Program for International Student Assessment (PISA) (OECD, 2014) focus almost exclusively on cognitive skills, hard skills, with soft skills measured only for the contextual information they provide to facilitate interpretation of hard skills results. This chapter addresses assessment of general, soft skills, specifically, interpersonal and intrapersonal skills.

Terminology issues

Terminology has been a longstanding problem and a source of confusion in this field. On one side—the noun side of the description—*skills*, *abilities*, *dispositions*, *competencies*, *attributes*, *traits*, *factors*, *constructs*, and *dimensions* are used, sometimes interchangeably. Factors and dimensions are substantively neutral terms derived from the mathematical modeling of item responses and scale scores, particularly factor analysis, which has been a dominant approach used in interpersonal and intrapersonal assessment. But as technical terms, they are probably less frequently used than others. Traits is a widely used term in personality psychology, and in psychometrics it reflects mathematical modeling (e.g., item-response theory), but traits is also used in genetics, and therefore is sometimes incorrectly assumed to suggest a permanent, inherited disposition. Disposition also tends to be associated with permanence. Abilities tend to be associated with cognitive factors, such as general, verbal, spatial, reading, and mathematical abilities, and less so with the attributes discussed in this chapter, but references to noncognitive abilities can still be found (Lindqvist and Vestman, 2011). *Attitudes*, *values*, *beliefs* (or *mindsets*), and *behaviors*, are narrower terms that define smaller classes of psychological constructs. *Constructs* itself is a neutral, and broader term used in psychology to label behavioral domains, including but not limited to interpersonal and intrapersonal behavior. Attributes are neutral, but overly broad, for example, attributes can include features such as hair color. Competencies is a popular descriptor. Skill is a term used in psychology (Anderson, 1983) and philosophy (Ryle, 1946) to represent acquired procedural knowledge (“knowledge how”) as distinct from declarative knowledge (“knowledge that”), and as distinct from abilities, which are assumed less malleable. Thus, skill reflects the notion of a malleable psychological attribute.

On the other (adjective) side of the description, terms such as *soft*, *interpersonal* and *intrapersonal*, *21st century*, *personality*, *noncognitive*, *character*, *behavioral*, *transversal*, and other descriptors (including the term *other*) are also used, sometimes interchangeably, as modifiers of skills, traits, abilities, competencies, factors, and the like. *Soft skills* is a term widely used in the workforce, social-emotional and character skills are terms used in K-12 education, transversal is used by UNESCO, psychosocial and interpersonal and intrapersonal are used in higher education, 21st century is a term describing a change in the kinds of tasks people perform due to the change from a manufacturing to an information economy, noncognitive has been used widely in economics (although

with origins in psychology (Messick, 1979)), and personality by a branch of psychology. Although there are nuances in their distinctions, in general those nuances are not universally understood, and thus these terms can mostly be understood as interchangeable even though some constituencies may argue about the nuances.

What are the interpersonal and intrapersonal skills?

There are many, different, and varied interpersonal and intrapersonal skills. Peterson and Seligman (2004) list 24 interpersonal and intrapersonal skills, which they refer to as “character strengths” (e.g., bravery, love, teamwork, forgiveness) organized as 6 “virtues” (wisdom, courage, humanity, justice, temperance, transcendence). The Collaborative for Academic, Social, and Emotional Learning’s (CASEL) Assessment Guide (2018) presents 28 assessments (from ACT TESSERA to ZOO U) measuring 157 different “SEL Competencies,” from “academic motivation,” “behavioral self-control,” “classroom effort,” “decision-making,” and “future orientation” to “vision” and “zest.” The RAND Education Assessment Finder (Schweig et al., 2018) provides an even more exhaustive list of 98 interpersonal and intrapersonal assessments, each of which provides “subscores” (typically 6–10) measuring various “constructs.” The National Research Council (2012) compiled many sources of lists of such constructs. Kyllonen (2016) compiled lists of various noncognitive skills, attitudes, values, and beliefs from various sources including personality psychology, economics, social attitudes, values, cross-cultural psychology, and others. Trilling and Fadel (2009) compiled a list of 184 “21st century skills” from various sources.

This is a confusing and overwhelming set of constructs. This is particularly so because some constructs go by different names and some names stand for different constructs, a long-recognized phenomenon in psychology referred to as jingle-jangle fallacies (Kelly, 1927, p. 64). There have been several approaches to organizing or categorizing such constructs and placing them into a more manageable framework (Blythe and Borowski, 2018; Berg et al., 2017). CASEL (Durlak et al., 2011, 2015) has proposed an organizing heuristic comprising five categories of constructs—self-awareness, social awareness, self-management, relationship skills, and responsible decision making. The basis for the framework is to enable easy categorization of skills themes in intervention programs (CASEL, 2005). Because of CASEL’s influence in the social emotional learning field, this framework has been quite influential. Another influential categorization comes from the Consortium of Chicago Schools research (Farrington et al., 2012), which proposes 5 categories of “noncognitive factors”—academic behavior, academic perseverance, academic mindsets, learning strategies, and social skills, each of which comprises several narrower factors (e.g., study skills, metacognitive strategies, self-regulated learning, time management, and goal setting as narrower learning strategies factors)—on the basis of evidence that such factors are malleable and relate to academic outcomes. Jones et al. (2019) provided a crosswalk between frameworks, based on expert judgments of similarity between factors from various frameworks.

An alternative to the rational frameworks is the Big 5 model from personality psychology. The model proposes five orthogonal factors—Conscientiousness, Extraversion, Agreeableness, Neuroticism, and Openness—retrievable with the use of the mnemonics OCEAN or CANOE. The Big 5 model is based on the lexical hypothesis, that language has evolved to encode the most salient differentiating characteristics of people in the form of words—such as assertive, generous, organized, insecure, and creative (Goldberg, 1993; John et al., 1988; Saucier and Ostendorf, 1999). A factor analysis of self-ratings based on such words results in five dimensions. This result has been replicated across a variety of languages (Saucier et al., 2000). Saucier and Iurino (2020) recently pointed out that the five-factors are not necessarily the best characterization of the structure of language, at least in English, and that as many as 21 dimensions may be justified. Although the more elaborated structures are probably not as robust, particularly cross-culturally (Lui et al., 2020), there are advantages in predictive capacity for a more high-dimensional model (Paunonen and Ashton, 2001).

Although the lexical hypothesis gave rise to the Big 5 model, the same five dimensions have been found to capture the structure of statements as well as words (e.g., “I am a hard worker,” “I enjoy thinking about the origins of the universe,” “I ask a lot of questions in class”) (John and Srivastava, 1999). Cross cultural generalizability also is present for statement-based measures (Heine and Buchtel, 2009). There have been attempts to discover additional dimensions beyond the Big 5. Drasgow et al. (2012) proposed a “lower order trait taxonomy” empirically identified, comprising several facets of the Big 5 factors, for example, achievement, order, self-control, responsibility, non-delinquency, and virtue as facets of conscientiousness. In addition, the taxonomy proposed 6 lower order Openness facets (intellectual efficiency, ingenuity, curiosity, esthetics, tolerance, depth), and three lower order facets for each of agreeableness (consideration, selflessness, cooperation), extraversion (dominance, sociability, attention seeking), and emotional stability (adjustment, even-tempered, optimism); a total of 21 factors (or facets). Similar efforts have arrived at somewhat similar set of factors (Condon, 2018, found 27 factors; Soto and John, 2017 identified 15 factors; Lee and Ashton, 2004, identified 24 factors). Notably, Primi et al. (2021b) identified 18 factors, and provided a crosswalk to the CASEL and Chicago consortium frameworks, the Soto and John (2017) framework, and a framework used by the Office of Economic Cooperation and Development (OECD; Kanakas and Suarez-Alvarez, 2019, Table 1, p. 3). Soto et al. (2022, (see also Soto et al., 2021) suggest a framework (including a 192-item assessment derived from the framework), that unites many of these frameworks.

The value of the Big 5 and to a smaller extent, its extensions into lower order factors (sometimes referred to as *facets*), is that it serves as a standard framework. It has become a standard because it is based not on experts’ rational judgments, but on empirical relationships (correlations) between self- (and other-) evaluations based on words and statements. That is, people who describe themselves as hard-working tend to also describe themselves as able to meet deadlines. But they are equally likely to be curious or incurious. The five factors and associated facets emerge from the analysis of this pattern of predictive relationships.

There are many advantages to standards, such as the Big 5. One is that meta-analyses can be done based on the framework. The Big 5 makes it possible to classify findings from studies, for example prediction studies of Big 5 factors with academic outcomes. Some studies might not use Big 5 terminology (e.g., Robbins et al., 2004; Richardson et al., 2012), but can still be classified as Big 5 studies in meta-analyses because of the known relationships between the factors used in such studies and Big 5 factors. For example, Robbins et al.'s (2004) "achievement motivation," and Richardson et al.'s (2012) "motivational factors" can be treated in a meta-analysis, such as Poropat's (2009), as measures of conscientiousness for the purpose of estimating the strength of relationship between conscientiousness and academic outcomes. The proliferation of factors identified in the beginning of this section, without a standard such as the Big 5, works against such compiling of studies and the resultant accumulation of knowledge. Further research might begin standardizing on the more specific facet dimensions of the Big 5.

A second advantage is that the standard, the Big 5, becomes a way to understand how concepts fit into a larger picture of the ways people differ generally and to address the issue of the jingle-jangle fallacy. Credé et al.'s (2017) analysis of Duckworth's (2016) grit factor as a measure of two facets of conscientiousness (perseverance of effort, which is responsible for most of the academic outcome predictions, and consistency of interest) is a case in point. Another nice illustration of this organizational capability of the Big 5 is a study by John and Mauskopf (2015) (John and De Fruyt, 2015) in which students were asked to rate themselves on the 157 21st century skills from Trilling and Fadel (2009). A factor analysis of those ratings resulted in a structure remarkably close to the Big 5. In such a way, the Big 5 is a useful organizing framework.

One limitation of the Big 5 model is that although it is based on data, it is based exclusively on correlational data, with correlations limited to those from a specific form of assessment, primarily self-ratings of descriptors and statements, with some research from others' ratings. Based strictly on correlational data, a question is whether the factors identified in the Big 5 are important for human (and student) development. We know that the Big 5 factors are useful metrics for describing an individual (self-description or other description), and useful for predicting outcomes, such as academic, workforce, and life outcomes (see next section, **Interpersonal and intrapersonal skills predict academic outcomes**). But are the Big 5 factors useful for diagnosing individuals and organizing and adapting treatments (interventions), for example? Would training targeting Big 5 factors result in individual changes in those Big 5 factors? Recall that the CASEL framework emerged from attempts to categorize treatments. Is there comparable value in using the Big 5 to categorize treatments? Or is there an alternative that similarly to the Big 5 has an empirical basis that might be used to categorize treatments and target interventions?

A study that addressed that issue was conducted by the National Academies of Science, Engineering, and Medicine (NASEM, 2017), which was given a charge "to more clearly define interpersonal and intrapersonal competencies, to examine whether and to what extent a range of these competencies may be related to each other and to persistence and success in undergraduate education (especially in STEM) and to examine the extent to which these competencies can be enhanced through intervention" (p. 2). The study identified 8 competencies—*behaviors related to conscientiousness, sense of belonging, academic self-efficacy, growth mindset, utility goals and values, intrinsic goals and interest, prosocial goals and values, and positive future self*. Several of these could undoubtedly be aligned to Big 5 factors (the first to Conscientiousness; prosocial goals and values to Agreeableness; sense of belonging, growth mindset, and academic self-efficacy to the Neuroticism factor in the Big 5 according to Judge et al., 2003). Unfortunately, although the proposed 8-factor taxonomy may be useful for categorizing research that has been shown to identify "promising competencies that appear to be related to college success" (p. 4), the taxonomy is limited as a guiding framework for organizing soft skills for a couple of reasons. First, all 8 competencies are intrapersonal competencies—the committee identified no interpersonal competencies (e.g., social skills) associated with success in higher education, and therefore leaves out an important aspect of human skill. Second, as the committee pointed out, the criteria for inclusion were strict, leading to the conclusion that "Only limited research has been conducted to date on the potential relationships between various intra- and interpersonal competencies and students' college success. There are major gaps in the research evidence" (p. 4). Thus, although suggestive, and a useful moment-in-time summary, the NASEM (2017) taxonomy is of limited usefulness for characterizing the nature of interpersonal and intrapersonal competencies.

Findings related to interpersonal and intrapersonal skills

Interpersonal and intrapersonal skills predict academic outcomes

Interpersonal and intrapersonal skills are correlated with academic outcomes such as grades in school. This has been demonstrated at all levels of education, primary (elementary), secondary (high school), and tertiary (college). The correlation, based on a meta-analysis (Poropat, 2009), is at least modest, in the $r = 0.20$ s range. The correlation is only slightly lower than the correlation between cognitive ability tests and grades, which Poropat reported as $r = 0.23$. The correlation estimate, particularly for Conscientiousness seems not to depend on the measure used (McAbee and Oswald, 2013). A more recent and more comprehensive meta-analysis (Mammadov, 2022; see also Zell and Lesick, 2021) supports the key findings of Poropat's analysis: Interpersonal and intrapersonal skills, specifically, all the Big 5 personality dimensions, predict school performance across all levels of school. The two highest correlates were conscientiousness (being hard-working, self-disciplined, and responsible), with a correlation of $r = 0.27$ and openness (being curious, creative, and open-minded) with a correlation of $r = 0.16$ (both correlations corrected for measurement error, but not for range restriction). The strong correlation with conscientiousness did not decline with education level, but the correlation of school performance with openness did decline with education level, from elementary to secondary to post-secondary, where it was smallest. Cognitive ability also predicted school performance ($r = 0.42$), but controlling for cognitive ability, there was still a strong relationship between school performance and conscientiousness. The correlation with openness,

controlling for cognitive ability mostly disappears, suggesting that the relationship between openness and school performance is mostly explained by cognitive ability, which is not surprising given that some openness items are merely self-assessments of one's academic abilities. The importance of conscientiousness (and openness), particularly in higher education, has been found in other meta-analyses (O'Conner and Paunonen, 2007), along with the finding that extraversion (being social, outgoing, and socially dominant) was sometimes negatively related to academic success.

Meta-analyses, such as those just reviewed, are useful for estimating the strength of association between inter-intrapersonal skills and school performance, but a weakness is that they combine many different measures in diverse settings, which might distort the relationship between the constructs. Large-scale studies conducted with common measures in relatively homogenous contexts provide useful supplements to the meta-analyses. Such studies support the findings from the meta-analyses. For example, California's Office to Reform Education (CORE) Districts administered assessments of four noncognitive skills—self-management, growth mindset, self-efficacy, and social awareness—to over 400,000 students in grades 3–12 in over 1200 schools in 8 California school districts in a couple of successive cohorts (2014, 2015). All skills measures correlated positively with measures of academic performance (GPA and state test scores) and negatively with suspensions and absences (West et al., 2018a,b).

Similar results were obtained in a study of District of Columbia Public Schools (DCPS) by Kautz et al. (2021). In this study, over 43,000 students were administered a set of interpersonal and intrapersonal (social-emotional learning, or SEL) measures (perseverance, self-management, self-efficacy, social awareness) and school experiences (i.e., climate) (rigorous expectations, sense of belonging, student satisfaction) which were correlated to a set of outcomes (achievement, attendance, suspensions). The highest correlate was self-management, which correlated $r = 0.23$ with Math and ELA achievement, and with number of AP credits ($r = 0.18$) and on-time graduation ($r = 0.16$). SEL measures did not add to the prediction of these outcomes when demographics and prior year academic measures were included in the prediction of current year academic measures.

This relationship between soft skills and academic outcomes is not limited to the United States. Brazilian researchers (Primi et al., 2021a,b) developed a battery from existing measures that factor analyses showed aligned with the Big 5 (while also including an additional locus of control factor; Santos and Primi, 2014, Table 4). The assessment has been administered to over 600,000 Brazilian students (Ricardo Primi, personal communication, December 2021). Prediction studies showed that the Big 5 factors correlated with both math and language achievement in the moderate ranges close to what Poropat's (2009) and Mammadov's (2022) meta-analyses suggested (Primi et al., 2019) (Interestingly, the correlations were substantially higher for reverse-keyed items, that is items, such as "I miss deadlines," in which a negative response, such as "strongly disagree," is treated as a positive indicator of the trait).

Another major study on the relationship between inter-intrapersonal skills and academic outcomes was the Organization for Economic Co-operation and Development's Study on Social and Emotional Skills (Chernyshenko et al., 2018; Kankaras and Suarez-Alvarez, 2019; OECD, 2021), which was conducted with 10 and 15-year-olds in 10 cities around the world. The OECD assessment measured 15 factors, aligned to the Big 5 (3 facets per each of the Big 5 factors). The factors with the strongest prediction of reading, mathematics, and arts grades were persistence and curiosity (for both 10- and 15-year-olds), and negative correlations with stress resistance and sociability (for 15-year-olds), again, findings aligning with the results of the meta-analyses.

Interpersonal and intrapersonal skills predict non-academic outcomes

There have been many studies that have examined the relationship between interpersonal and intrapersonal skills measures and outcomes going beyond academic outcomes. Roberts et al. (2007) showed that personality predicted mortality (/longevity), divorce, and occupational attainment to a degree comparable to the prediction given by cognitive ability and socioeconomic status. The strongest correlate of longevity was conscientiousness (effect size of 0.09), but other Big 5 factors also were associated with longevity, perhaps partly as the authors suggest because conscientiousness is related to engaging in more healthy behaviors. The strongest correlates of avoiding divorce were emotional stability and agreeableness (in addition to a smaller relationship with conscientiousness). The strongest correlates of occupational attainment (i.e., occupational status, typically indicated by average earnings and amount of education required) were four of the Big 5 with an average beta weight of 0.23, comparable to cognitive abilities (beta = 0.27) and socioeconomic status (beta = 0.09) and parental income (beta = 0.14).

Almlund et al. (2011) and Heckman and Kautz (2014) document a wide variety of relationships between personality and labor market outcomes (e.g., job performance, wages, job search effort), along with health and crime and school outcomes (e.g., attainment, attendance, course difficulty, grades, high-school graduation, test scores). Summaries of this line of work are found in OECD (2015, 2021) and Chernyshenko et al. (2018), and the fact of these documented relationships is what motivated OECD's (2021) Survey of Social Emotional Skills. Wilmot and Ones (2019) reviewed 92 meta-analyses (2500 studies involving over a million participants) concerning the relationship between personality and a variety of occupational outcomes, focusing on conscientiousness (see Zell and Lesick, 2021, for a similar quantitative synthesis of over 50 meta-analyses). Conscientiousness is the most predictive interpersonal-intrapersonal skills variable, and Wilmot and Ones showed that this predictiveness extended over 10 clusters (or themes) of occupational variables, themes related to job performance, counterproductive behavior, leadership, organizational commitment, and others. They also found that conscientiousness was most important in certain sectors, notably Health Care, the Military, Sales, and Customer Service occupations.

Unlike the case with cognitive abilities, there are multiple, distinct interpersonal and intrapersonal skills

An important distinction between soft (social-emotional/interpersonal-intrapersonal) and hard (cognitive) skills is in the importance of a general factor. Cognitive skills, such as quantitative and verbal abilities, despite their apparent differences, tend to be highly correlated, a phenomenon noted since Spearman (1904) and Kelley (1927). For example, the program for international student assessment (PISA) finds that latent correlations between tests of mathematics, science, reading, problem solving, and financial literacy range from $r = 0.76$ to $r = 0.91$, with a median of $r = 0.86$ (OECD, 2014, pp. 230–231, Table 12.6, 12.7, 12.8). In fact, two mathematical subscale latent correlations are lower than this median (OECD, 2014, p. 231, Table 12.9). This suggests a strong general factor governing diverse measures of cognitive ability.

In contrast, although some have argued for a general factor in social emotional skills (Dunkel et al., 2021; Musek, 2007; Oltmans et al., 2018), a better characterization is that interpersonal and intrapersonal skills are strongly multidimensional: Being hard-working and intellectually curious are independent (i.e., orthogonal) characteristics of people, for example. The discussion of soft skills dimensionality in the previous sections (e.g., the Big 5 and its extensions) documents this evidence. There are several implications of this finding of multidimensionality for assessment. One is that social-emotional diagnostic modeling is likely to be more fruitful substantively than cognitive diagnostic modeling (CDM; Rupp and Templin, 2008) has proven to be so far. The original premise of cognitive diagnosis was that targeted training could be based on an individual's profile of knowledge and skill at any given moment. However, there is a large literature attesting to the lack of evidence for differentiation available from typical cognitive tests (Haberman, 2008)—total scores are typically more predictive of subscores than like subscores are (Sinharay et al., 2007). This is a cognitive ability phenomenon related to the strength of the general cognitive ability factor on cognitive test performance (combined with the effects of measurement error related to brief measures on prediction). There is not a comparable powerful general factor in soft skills assessment. Therefore, cognitive diagnosis modeling based on independent (not highly correlated) social emotional factors is likely to be a more productive pursuit.

Interpersonal and intrapersonal skills appear to change over time but not in exactly the same way cognitive skills do

On average, test scores, such as mathematics and language achievement scores, or intelligence test scores, rise steadily from early childhood to adulthood where they flatten out until a decline in old age, with some abilities (fluid intelligence) peaking earlier, and others (crystallized knowledge) later (McArdle et al., 2000). This reflects the accumulation of knowledge, skill, and experience over the life span. This can be seen in K-12 education as average achievement scores rise steadily and monotonically from grade to grade (e.g., Ugo and Hill, 2017, Figure 4, p. 9).

As with cognitive abilities, there does seem to be growth in many soft skills dimensions, particularly social dominance, conscientiousness, agreeableness, and emotional stability (Roberts and Mroczek, 2008; Roberts et al., 2006; Srivastava et al., 2003).¹ In that sense there is some similarity with cognitive changes that occur over the lifespan. Life events may also affect these trajectories both for cognitive (Deary, 2014; Nisbett et al., 2012) and noncognitive skills (De Vries et al., 2021; Jackson et al., 2012; Lüdtke et al., 2011).

The picture of development in childhood and adolescence looks quite different. Agreeableness, conscientiousness, and openness tend to decline in late childhood into adolescence, and incline from late adolescence into adulthood (Soto et al., 2011), although there may be some variations by gender in these patterns (Borghuis et al., 2017). The dip is not an artifact of self-reporting: The same decline is found in parent reports (Soto, 2016). Nevertheless, large-scale studies of social-emotional skills find much the same pattern of non-monotonic changes from childhood to late adolescence. Consider, for example, OECD's (2021) study on social emotional skills, which found that on 15 of the 17 scales evaluated, 15-year-olds scored lower than 10-year-olds by up to 0.6 of a standard deviation. The drop in scores was particularly strong in persistence, optimism, trust, curiosity, sociability, energy, and achievement motivation. In only two cases, tolerance and assertiveness, did scores rise, slightly, from age 10 to 15. In the California CORE study (Meyer et al., 2018; West et al., 2018b, 2020), growth mindset rose from grades 4 to 12, with a slight dip in grade 7; social awareness dropped substantially from grade 4 to a nadir in grade 8, rising slightly after that; self-management rose, then fell, then rose again during the grade 4 to grade 12 span; and self-efficacy fell from grade 6 through grade 10, with a slight upturn in grades 11 and 12. The DC public schools study (Kautz et al., 2021) similarly found that scores on all of the social emotional (perseverance, self-management, self-sufficiency, social awareness) and school experience (rigorous expectations, sense of belonging, student satisfaction) scales declined from age 8 (grade 3) to 16 (grade 9–10), gently rising to age 18 (grade 12) (Figure C1; see also Figure 1, p. 8). Interestingly, scales tended to fall and rise in unison rather than some going in one direction and others going in a different direction, which might be expected with multidimensionality. Considering all these studies, whether the findings reflect adolescence "Sturm und Drang" (storm and stress) (Hall, 1916), or are simply an artifact of measurement technique is unknown because all these studies have been conducted exclusively with rating scales. For example, some of the rise and fall of assessment scores based on rating scales during adolescence might be due to response style (e.g., the tendency to agree or disagree regardless of the question).

¹The studies have similar findings, but Srivastava et al. (2003) found that growth in emotional stability occurred only for women; Roberts et al. (2006) found that the social dominance but not sociability facet of extraversion grew over adulthood; Roberts and Mroczek (2008) showed increases in self-confidence, warmth, self-control, and emotional stability.

Interpersonal and intrapersonal skills can be improved

The previous section made the case for the malleability of interpersonal and intrapersonal (soft) skills, primarily due to the passage of time over the lifespan, but a question is whether soft skills improvement can be accelerated, for example through an intervention. In K-12 there is evidence for efficacy of social-emotional learning programs, both in-school (Durlak et al., 2011) and after school (Durlak et al., 2010). These effects appear to persist over time (Taylor et al., 2017). Such programs have been shown not only to affect the social-emotional skills that are the target of the programs, but also to affect behavior and achievement. Fricke et al. (2021) showed that schools themselves (school effects) might contribute to student social-emotional learning gains, particularly the schools in the top or bottom of the effect distribution, meaning that certain schools are good (or poor) at contributing to social-emotional skills development.

For adults, a meta-analysis by Roberts et al. (2017) found evidence for substantial improvement (effect size of $d = 0.37$) in personality measures following an average of a 24-week intervention, which persisted in follow-up data collections. Such intervention effects were particularly strong for anxiety, although other factors were also examined and showed differences. A limitation of this study is that because pre- and post-intervention measures were self-reports, demand characteristics (i.e., situational cues that indicate to the respondent what the experimenter expects or wishes to happen) might have influenced responding.

Interpersonal and intrapersonal outcomes in the studies cited above were typically measured by self- and other- (typically teacher) rating scales. However, the conclusion of the malleability of interpersonal and intrapersonal (noncognitive) skills is not dependent on studies that rely on rating scales. Kautz et al. (2014) review evidence from a variety of types of measures from a broad array of programs ranging from infant programs, early childhood programs, targeted non-cognitive skill programs, adolescent mentorship, and others on a wide range of academic and life outcomes. Jackson (2018) took the approach of computing two kinds of teacher effects for over 10,000 9th grade teachers in North Carolina: a cognitive teacher effect based on test scores (the variable used in typical teacher value added models) and a noncognitive teacher effect, which he referred to as the *behavioral index*, based on the average of a set of proxy variables—absences, suspensions, course grades, and grade repetition (these two sets of variables were correlated $r = 0.56$, with the behavioral index having a much stronger effect on high-school graduation). Jackson showed that the two kinds of teacher effects influenced subsequent outcomes differently: cognitive teacher effects influenced subsequent SAT scores; noncognitive teacher effects (conditional on teacher effects on test scores) influenced high school graduation and other longer run outcomes including subsequent grade-point average. Jackson et al. (2020) also found school effects on not only interpersonal-intrapersonal self-reports but also on school-based arrests, high school completion, and college enrollment and completion. Kautz and Zanoni (2019) similarly showed that a noncognitive composite of such measures was responsible for increased college enrollment due to an intervention program called *OneGoal*. These two studies represent some of the rare instances in which interpersonal-intrapersonal skills are assessed with behavior other than responses to rating scale items.

A question is whether an intervention designed to enhance interpersonal and intrapersonal (soft) skills can affect outcomes other than self-reports in adults. Within education, a major study showed smaller effects from a mindset intervention on college grades (standardized effect of $d = 0.11$, or $b = 0.10$ [i.e., one tenth of a grade point] in the grade point metric) (Yaeger et al., 2019). The National Academy of Sciences (2017) reviewed evidence for the effects of interventions targeting interpersonal and intrapersonal skills on academic persistence and success and identified numerous programs that did so (see their Table B-1). Solanki et al.'s (2020) meta-analysis of social-psychological interventions in college found moderate effect sizes, and that interventions tended to be particularly effective for at-risk student groups. Much of the evidence in these reviews comes from the United States. Leight (2021) reviewed evidence for efficacy of soft skills training on a variety of workforce and life outcomes outside the United States and identified several positive findings.

Organizations routinely conduct soft skills training for employees, often following Kirkpatrick and Kirkpatrick (2006) evaluation model, which successively examines attitudes toward the training, knowledge of the trained material, transfer of training to the workplace, and return on investment. Arthur et al. (2003) showed evidence for organizational soft-skills training efficacy for each of Kirkpatrick's stages. Martin-Raugh et al. (2020) reviewed 39 meta-analyses concerning the development of soft skills primarily in organizations. Intervention approaches varied and included modeling, goal-setting, character education, sports participation, adventure therapy, role-playing, and reward-based programs. They found at least some evidence for improvement of interpersonal skills (social skills, communication skills, leadership, teamwork) and intrapersonal skills (personality, job-related attitudes, self-concept and self-efficacy, emotions, motivation) from training. Effect sizes tended to be in the 0.2–0.5 standard deviation range. Thus, although there is a widespread belief that noncognitive skills or personality attributes are permanent and fixed, in fact there is considerable evidence for the malleability of such skills through interventions, and that such improvements transfer to outcomes other than self-assessments. Nevertheless, as was pointed out in the National Academies report (2017), the evidence for efficacy for many of these programs likely has been weakened by inadequate assessment of intervention effects.

There are some subgroup differences in interpersonal and intrapersonal skills, but they are smaller than and different from cognitive skill differences

Numerous studies have examined mean gender, race/ethnicity, and cultural subgroup differences in noncognitive skills. Smaller subgroup differences are observed on noncognitive skills measures (typically with Cohen's (1988) $d < 0.3$) compared to cognitive skills measures (often $d > 1.0$). For example, in K-12, gaps between the highest and lowest fifths of socio-economic status

distributions are typically over 1 standard deviation in reading and math, but only between one-third and one-half a standard deviation for self-control and approaches to learning (García and Weiss, 2017).

Also, the pattern of differences is more complex than it is with cognitive skills, with some groups scoring higher on some factors, and other groups higher on other factors. In adults including college students, women tend to be higher in neuroticism, extraversion, agreeableness, and conscientiousness, whereas men tend to be higher in assertiveness and openness to ideas (Costa et al., 2001; Schmitt et al., 2008). This pattern tends to hold up across cultures, although there may be slightly larger gender differences in gender equal countries (Mac Giolla and Kajonius, 2019). This pattern of gender differences, cross-cultural similarity, and age-related changes holds up with others' reports as well as self-reports (McCrae et al., 2005). Differences between sexes tend to emerge in adolescence (Brandes et al., 2021), with Neuroticism differences emerging by age 14, and little evidence for differences between cultures in either self-reports or parents' reports (De Bolle et al., 2015; Soto, 2016).

Regarding racial/ethnic subgroup differences, Foides et al. (2008) conducted a meta-analysis of personality scale differences comparing 5 U.S. subgroups, focusing on Big 5 and facet measures. They concluded that in general, race/ethnic group differences were small, with a few exceptions. The few at least moderate differences ($d > 0.2$) in which the lower and upper 90% CV did not contain zero, were anxiety (Black [B] higher than [>] White [W]), self-esteem (Asian [A] & Hispanic [H] > W), order (A > W), agreeableness (W > American Indian [AI]), emotional stability (B > A), extraversion (B > A), and sociability (H > B).

Also important in comparing subgroups is establishing measurement invariance, a statistical procedure to evaluate subgroup effects on item factors, item means, and item covariances, to ensure that scores from the measure can be interpreted in the same way regardless of the subgroup from which the score is obtained (Millsap, 2011). Only after ensuring measurement invariance can mean and correlation differences between groups be accurately interpreted. Although measurement invariance analysis has not been a universal practice for the past few decades, studies are beginning to include measurement invariance analyses as part of reporting of group and cultural differences (e.g., Cunha et al., 2021), and this practice ought to become a routine part of such reporting.

Others'-assessments of soft skills are more predictive of outcomes than self-assessments, but the two provide complementary, not duplicative information

In the immediately preceding section, a finding was that self-reports and reports by others resulted in similar correlational structures (correlational patterns to support the Big 5 model) and similar conclusions about gender differences, cultural differences, or lack of cultural differences, and age-related changes (McCrae et al., 2005). However, there is also evidence that self-reports and others' reports are not the same. In fact, correlations between self-reports and others' reports on the same construct are not necessarily that high. Corrected for measurement error, self-other correlations range from 0.46 for agreeableness and 0.62 for extraversion (Connolly et al., 2007), but that presents a rosy picture due to the correction. Without correcting for measurement error, the correlation tends to be much lower. For example, for ETS's Personal Potential Index (Kyllonen, 2008), a rating form in which multiple faculty members rated graduate school applicants on six scales (Knowledge & Skill, Creativity, Communication Skills, Teamwork, Motivation, Self-Organization and Professionalism & Maturity), McCaffrey et al. (2018) estimated that as many as 9–12 raters (depending on the scale) would be needed to obtain a generalizability coefficient (a measure of reliability) of 0.7. In the CORE study, Hough et al. (2017, Table 5, Table A3) found low correlations between students' perceptions of school culture and climate and parents' and staffs' perceptions: Correlations between culture and climate scales within a group of respondents were substantially higher than correlations of the same scale across respondent groups, although respondent groups tended to increase their similarity as they moved from elementary to middle to high school students. Kautz et al. (2021) found that student and teacher reports were only modestly correlated, for example $r = 0.24$ for perseverance and $r = 0.45$ for rigorous expectations (Figure 5, p. 13). Also, interpersonal and intrapersonal measures had different trajectories from elementary to high school, with student reports showing a dip from 5th to 9th grade and a shallow rise thereafter and teacher reports showing a steady decline from elementary through high school. ETS's Mission Skills Assessment (MSA), administered to over 13,000 middle school students and 1200 teachers, similarly found student-teacher correlations ranging from $r = 0.24$ (Resilience scale) to $r = 0.43$ (Time Management scale) for 6 MSA scales (Petway et al., 2016).

The relatively modest size of self-other correlations and the difference in trends suggests different information carried in student and teacher reports. A question is which one is more accurate, or at least, which one is more predictive of future outcomes? In K-12, Poropat (2014) showed that others' (teachers) ratings were more predictive of student academic outcomes than self-ratings were. Feng et al. (2022) similarly found that teacher reports were most predictive of children's achievement and behavioral outcomes in school and neither children self-reports nor guardian reports added much to the prediction. They suggest this advantage of teacher reports may be due either to teachers' ability to calibrate due to their exposure to many children, to halo effects that incorporate students' achievement, or to teachers' judgments being limited to the school context, which is the context in which the outcomes occur. Lindqvist and Vestman (2011) attributed their relatively high predictions of 20-year-later labor market outcomes to the use of ratings by others (in this case, experts) versus the more typical self-ratings. Segal (2013) showed that teacher ratings of 8th grade students' noncognitive behavior predicted long-term outcomes, including earnings above and beyond the prediction given by test scores, and that noncognitive behavior predicted earnings at all education levels unlike test scores, which predicted earnings only for postsecondary degree holders.

In the adult literature, Oh et al. (2011) found that others' reports of the Big 5 were stronger predictors of job performance than self-reports were, and that others' reports added substantially to the prediction given by self-reports of job performance for all 5 of

the Big 5 scales (the reverse was not true). Prediction benefit increased incrementally with the number of raters (from 1 to 3). Connelly and Ones (2010) similarly found others' reports to be substantially better than self-reports for predicting outcomes, and that there was a benefit of familiarity with the target of rating, but even relatively modest familiarity was useful for predicting others' behavior. Like McCaffrey et al. (2018) they also suggested that numerous raters, perhaps 5–10, were required to reach typical interrater reliability standards. Nevertheless, Klieger et al. (2022) found in examining doctoral STEM programs using standardized ratings from ETS's Personal Potential Index (PPI) that two dimensions—Planning and Organization (a conscientiousness dimension) and Communication Skills positively predicted school grade point average and lower risk of academic probation controlling for undergraduate grade-point average and Graduate Record Examination (GRE) scores. The PPI also showed considerably smaller mean race/ethnicity and gender differences than undergraduate grade-point average and GRE scores.

Letters of recommendation also have been proposed as a means for obtaining information about noncognitive skills of students and applicants by others. Some research has suggested that there is useful information in letters of recommendation, albeit weak (Kuncel et al., 2014). A recent large study, which analyzed 37,000 letters of recommendation (Dalal et al., 2022) found that letters do not predict admissions offers, after GRE scores and undergraduate GPA is considered, and that there was evidence for effects on the content of the letters attributable to gender, race/ethnicity, and program level applied to (masters vs. doctoral). This suggests that the standardized letter approach in Klieger et al. (2022), which found stronger relationships than those found by Kuncel et al. (2014) and Dalal et al. (2022) might be advantageous over the conventional, and much more common unstandardized letter approach.

Noncognitive and cognitive skills are distinct but they overlap and are difficult to disentangle

Many of the discussions in this field concern the relative importance of cognitive and noncognitive skills to academic and workforce success, as well as to other outcomes. This is an important topic because from an educational assessment perspective, it is important to monitor development and growth of skills, both cognitive and noncognitive, to ensure students are on track. Most attention in such monitoring has been on cognitive skills (e.g., state accountability tests, which began in the 2000s, national and international monitoring assessments such as the National Assessment of Educational Progress, which began in the 1980s, and the Program for International Student Assessment, which began in 2000). Only recently has there been comparable attention given to noncognitive skills development from a large-scale assessment standpoint (OECD, 2021). The importance of cognitive and noncognitive skills also is an important topic from a policy perspective as it may inform where educational investments might best be placed.

There have been attempts to tease apart the effects of cognitive and noncognitive skill on education, labor market, and life outcomes (Bowles et al., 2001; Duckworth et al., 2012), but a problem is that test scores are not pure, stable measures of constructs. A test score can reflect cognitive ability if all respondents are equally and highly attentive and motivated. But a test score may reflect something else, such as the degree to which one is typically motivated to take tests, if all respondents are not equally and highly attentive and motivated (Borghans et al., 2008). Soland (2018) evaluated the degree to which test effort differences could account for achievement gaps. Segal (2012) showed that motivation as indicated by applying effort on low-stakes test is a driving factor for long-term economic success. Kyllonen and Kell (2018) discuss numerous such potential confounding influences on test scores, and similarly confounding cognitive ability influences on noncognitive assessment responses and scores.

Uses for interpersonal and intrapersonal skills assessments

There are many ways in which interpersonal and intrapersonal skills assessments might be used (Kyllonen et al., 2005). Perhaps the three most significant use categories are selection (e.g., college admissions, scholarship reward, job recruitment and selection), student development (e.g., counseling, study skills coursework, leadership development program), and educational system monitoring (e.g., program evaluation, large-scale domestic or international assessment). These use cases vary on several dimensions, which has implications for assessment. The selection use is high stakes, which means that respondents' scores may affect consequential decisions made regarding them, such as whether they are admitted to a particular program, receive a scholarship, or get hired for a job. In these cases, respondents may be motivated to fake on the assessment or receive coaching on how to do so, and so the assessment should be resistant to such attempts. Also, for high-stakes assessments a premium is put on the psychometric properties of the test, that it is reliable, valid for the selection use, and fair, in the sense that the scores can be interpreted in the same way for all users and user subgroups. The AERA/APA/NCME (2014) *Standards for Educational and Psychological Testing* defines high stakes as "a test used to provide results that have important direct consequences for individuals, programs, or institutions ..." (p. 219) and documents the stringent evidence standards needed for this high-stakes use. Naemi et al. (2014) describe a multidimensional forced-choice assessment of noncognitive skills designed for graduate and professional school admissions and workforce personnel selection that falls into this category. Tannenbaum and Kane (2019) argue that there are less-than-high-stakes uses in which some of these stringent standards might be relaxed somewhat. An example might be the case of a placement tests for remedial versus regular instruction.

The development use is generally considered to be low-stakes because one's test scores will not affect consequential decisions about the individual but are instead designed to help the individual develop. AERA et al. (2014) defines low stakes as "a test used to provide results that have only minor or indirect consequences for individuals, programs, or institutions" Here, faking and coaching are not concerns and instead feedback, such as normative feedback, or formative feedback is useful, and suggestions

tied to scores and score profiles are valuable. GMAC's (2013) Reflect™ tool, which was a Likert-scale survey measuring 10 key competencies (innovation, operational thinking, decision-making, strategic vision, strategic self-awareness, resilience, drive, interpersonal intuition, valuing others, and collaboration) is an example of such an assessment. It provided a personalized action plan, library, and benchmarking data from 14 jobs, information designed to prepare business school students for the workplace. ETS's SuccessNavigator™ (Burrus et al., 2013; Markle et al., 2013), was similarly a low-stakes guidance tool, but here the primary application was to serve as an early alert for students who were at risk of leaving college.

The system monitoring use is also low-stakes, at least for the individual test taker. However, in monitoring uses, the data are typically used in policy decisions and so data quality at least at the aggregate level is important. For this application individual scores do not even have to be produced, and a group scores approach can be taken (Mazzeo et al., 2006). For example, different respondents can receive different item subsets, as was done in the DCPS study (Kautz et al., 2021) and is routinely done for measuring cognitive abilities in large-scale assessments such as NAEP and PISA.

Approaches for assessing interpersonal and intrapersonal skills

There are many approaches to assessing interpersonal and intrapersonal skills. However, the predominant approach is ratings, either self-ratings or ratings by others. In this section the ratings approach is reviewed along with several other approaches, which are particularly popular, useful, or promising: multidimensional forced-choice self-assessments, situational judgment tests, and performance tests.

Ratings

Almost all the evidence for the relationship between student social-emotional skills and academic performance is based on ratings, and for students in middle school and above, the vast majority of these are self-ratings (for young students and early childhood targets, teacher or care-giver ratings are the norm) (See McKown et al., 2021, for an exception.). The predominance of ratings and self-ratings can easily be seen in a search through the RAND Assessment Finder (Hamilton et al., 2018), which allows filtering on assessment method. Table 1 provides examples of rating scale items.

Ratings have several problems (Wetzel et al., 2016). Self-ratings are susceptible to reference-group, response style, and social desirability bias. Reference group bias refers to the bias induced by one's reference group—the group to which one compares oneself—when doing a self-evaluation (although this can also apply to others' ratings, it is most often cited in discussions of self-ratings). For example, consider the CORE Self-Management item "I came to class prepared" (the first item listed in Table 1). The

Table 1 Examples of interpersonal-intrapersonal items measuring different constructs.

Assessment	Construct	Instructions/framing statement	Item statement	Response categories
CORE	Self-management	Please answer how often you did the following during the past 30 days. During the past 30 days ...	I came to class prepared.	Almost never/once in a while/ sometimes/often/almost all the time
CORE	Social awareness	Please answer how often you did the following during the past 30 days. During the past 30 days ...	How often did you compliment others' accomplishments?	Not carefully at all/slightly carefully/ somewhat carefully/quite carefully/ extremely carefully
NAEP	Motivation/performance goal	How much does each of the following statements describe a person like you? Select one answer choice on each row	I want to look smart in comparison to the other students in my math class.	Not at all like me/a little bit like me/ somewhat like me/quite a bit like me/very much like me
ETS SN	Social support/connectedness	Please indicate how often each of the statements below applies to you. Please answer each statement separately and honestly.	I feel connected to my peers.	Strongly disagree/disagree/slightly disagree/slightly agree/agree/ strongly agree
PISA 2012	Sense of belonging	Thinking about your school: to what extent do you agree with the following statements? (Please darken only one circle in each row)	I feel happy at school	Strongly agree/agree/disagree/ strongly disagree
BFI-2	Open-mindedness/esthetic sensitivity	I am someone who ...	___Has few artistic interests.	Disagree strongly/disagree a little/ neutral: no opinion/agree a little/ agree strongly

Notes. CORE = California Office to Reform Education (West et al., 2018a); NAEP = National Assessment of Educational Progress (2018) Pilot Mathematics Student Grade 12 (Item 24; NCES, 2018); ETS SN = Educational Testing Service Success Navigator (Markle et al., 2013); PISA 2012 = Student Questionnaire from the Program for International Student Assessment (OECD, 2013; NCES, 2012 [Q40g, Form B]); BFI-2 = Big Five Inventory Version 2 (Soto and John, 2017).

reference group argument is this: There is leeway in the definition of “prepared” and so to answer this, respondents at least implicitly compare themselves to others in class with respect to their level of preparedness. If the respondent is relatively more prepared than classmates “sometimes” or “often,” then they will respond accordingly. But note that this judgment depends on the classmates. Being surrounded by a set of always highly prepared classmates might cause a respondent to judge themselves as relatively unprepared (or to select, for example, the “once in a while” category). That identical level of preparedness, in the context of being surrounded by classmates who themselves are usually unprepared, might warrant an “often” or “almost all the time” response. Different respondents have different reference groups and thus a response given by two respondents is not strictly comparable. Methods such as anchoring vignettes (King and Wand, 2007; King et al., 2004), behaviorally anchored rating scales (Klieger et al., 2018), and Rasch/Guttman Scenario Scales (Ludlow et al., 2020a,b) are attempts to create a common metric to enable comparisons across individuals through anchor items. Kyllonen and Bertling (2014) and He et al. (2017) demonstrated the efficacy of anchoring vignettes in PISA 2012.

Response style bias refers to influences on responding that are independent of the construct being measured, including acquiescence (tendency to agree to statements), extreme response style (tendency to choose the endpoints of the response scales, such as “strongly agree,” “strongly disagree”), and modesty (tendency to choose the middle point[s] in a rating scale). There are useful statistical corrections for some of these (Primi et al., 2019).

Others’ ratings—in which a peer, instructor, advisor, or supervisor is asked to rate an individual student or applicant (e.g., “Please rate the applicant relative to others ... can overcome challenges and setbacks”; from Kyllonen, 2008)—also at least somewhat mitigate the biases in self ratings. But others’ ratings have their own problems, particularly halo/horn effects, which are revealed in high correlations among ratings on disparate attributes, ones that might be expected to have lower correlations (Klieger et al., 2022; McCaffrey et al., 2018).

Multidimensional forced-choice (ranking)

Multidimensional forced-choice (MFC), or ranking methods are alternatives to ratings, designed to mitigate some ratings biases. Response style biases are eliminated because of the choice format. In an MFC item, two (or more) statements are presented together and the respondent is asked to choose which of the two statements better characterizes them, is more true of them, or they agree with more. For example, considering items from Table 1, a respondent might be asked which of two statements better characterizes them: “I came to class prepared” or “I feel connected to my peers.” It is multidimensional because the two statements reflect different dimensions—in this example, self-management and connectedness, respectively. In a ranking version of the task, the respondent is asked to rank the statements (e.g., three, four, or even more statements) with respect to level of agreement with them. Social desirability is addressed by having respondents choose between different statements, where statements are balanced for social desirability (typically, social desirability is assessed in a separate study in which respondents are asked to evaluate the social desirability of the statements, or to select or rate statement that would maximize their chances of getting admitted, getting a scholarship, or getting the job).

Simple sum scoring of forced-choice and ranking methods—in which a dimension score is the sum of the number of times a statement from that dimension is selected—produces what is known as *ipsative* data. With ipsative data respondents may have different dimension scores, but all respondents have the same total score (sum of dimension scores). Ipsative data results in several undesirable measurement properties: it is impossible to have all high or all low dimension scores, correlations between dimension scores must sum to zero, correlations with external measures must sum to zero, and internal consistency reliability estimates are distorted (Brown and Maydeu-Olivares, 2013). Ipsative data with a low number of dimensions results in dimension scores that are negatively correlated, and this can render a factor analysis of item responses uninterpretable. All these properties lie in contrast to the properties of *normative* data, which is the type of data produced by rating scales. Normative data do not constrain scores: it is possible to be high or low on all dimensions, correlations with other dimensions or with external variables do not sum to be zero, and in general, psychometric analyses such as factor analysis and internal consistency reliability produce results that are interpretable.

However, it is not necessary to use simple sum scoring for MFC tasks. Item-response theory (IRT) methods, alternatives to classical sum scoring methods, have been developed that produce normative scores from forced-choice or ranking item responses. It is possible to use IRT scoring approaches for MFC items that produce scores with normative properties, overcoming the problems of ipsative data (Brown and Maydeu-Olivares, 2013; Stark et al., 2005).

There is evidence that forced-choice methods successfully mitigate socially desirable responding (Cao and Drasgow, 2019). There is also evidence that treatments of forced-choice responses that produce normative data, such as the IRT scoring approach or other quasi-ipsative methods (Salgado et al., 2014), result in stronger predictions with outcomes compared to purely ipsative methods or rating scale methods (Salgado and Tauriz, 2014; Salgado et al., 2014). This is an active area of psychometrics development (Brown and Böckenholt, 2022; Bürkner, 2022).

Situational judgment test (SJT)

One alternative to ratings and rankings of statements is the situational judgment test (SJT), which presents a situation and asks the respondent to indicate how they would respond to the situation, or what the best response to the situation would be (can be multiple choice, option ranking, option rating, or short answer). This form of assessment has been used in high stakes admissions

assessments, for business school (Hedlund et al., 2006), medical school (AAMC, 2021), and others. There is an active literature on the kinds of constructs that can be measured with SJTs (Christian et al., 2010) and what the best scoring methods are (De Leng et al., 2017; Zu and Kyllonen, 2020).

Performance tasks

Another alternative to ratings and rankings is a category that might be called performance tasks, in which actual performance is observed and treated as an indicator of various soft skill dimensions. This includes collaborative problem-solving tasks (von Davier et al., 2017), *real effort* tasks (tasks such as repetitively moving objects on the screen with a mouse as an indicator of effort) (Charness et al., 2018), and economic and other games (Falk et al., 2016), and includes both response and process analysis of performance (Hao et al., 2017). These tasks are attractive because they measure actual performance rather than self (or other) assessments of performance, assessments which, as noted earlier, are subject to various biases. Performance measures are often found to be weakly correlated with self-reports (Dang et al., 2020). This may be because performance measures do not achieve the reliability and other psychometric properties traditional questionnaire measures do (Boon-Falleur et al., 2022), but these are early days and we can expect this to be a growing area of continued research.

Conclusions

Considerable research conducted over the past two decades has demonstrated the importance of interpersonal and intrapersonal skills—noncognitive skills, social emotional competencies, personality, or soft skills—on education, workforce, and life outcomes. Consequently, there has been a push to assess these skills in students and workers at all levels, for a variety of purposes, including selection, personal development, and system monitoring. For example, there has been steady growth in the use of interpersonal and intrapersonal skills assessment in hiring (Meinert, 2015), and in offerings in soft skills training for development (Kyllonen et al., 2021), and the OECD (2021) just launched a new comparative (monitoring) study to assess social and emotional skills in cities around the world. This is a dramatic change from the situation two decades ago, when the focus of assessment attention had been almost exclusively on cognitive skills for the purposes of selection, student development, and educational system monitoring. Part of this change reflects growing evidence for the importance of interpersonal and intrapersonal skills; part of the change reflects a more sophisticated understanding of and more sophisticated approaches for assessing such skills.

Many challenges remain. Terminology is a source of confusion and likely will remain that way because different research and application sectors have different terminology preferences. Assessment can serve an important role in standardization through empirical findings: The Big 5 emerged to provide standardization in terminology because of recurring empirical findings of the relationships among certain kinds of self-evaluations despite a wide variety of words and statements used to describe behavior, attitudes, and beliefs. Another challenge is that the dominant assessment methodology is the rating scale, by self or by other, and rating scales have well documented limitations. Future research on the use of actual performance measures, direct or indirect, will likely prove fruitful, and should elevate the status of noncognitive skills assessment to the level of cognitive skills assessment. Performance tasks, including games, real effort tasks, and collaborative tasks and process analysis of performance on such tasks have the potential to overcome the limitations of self-reports, which make comparability over time and across contexts problematic, and prevent unambiguous statements about student growth and development. There is even now skepticism about the interpretability of noncognitive assessment scores, due to reference bias, response style effects, and social desirability and “faking good” bias, phenomena related to the use of rating scale measures (Ziegler et al., 2011). The development of performance measures of interpersonal and intrapersonal skills is rare relative to rating scale measures, and there are many challenges in developing such performance assessments. Still, it is likely that if evaluations of math, reading, and science achievement depended on self-assessments the field of educational assessment would not have the influence on policy and practice that it currently enjoys. Analogously, it is likely that only by moving interpersonal and intrapersonal assessment from ratings to performance will score users and stakeholders become satisfied with the information from such assessments.

Importance of collaborative problem solving

Changes in our world (e.g., demographic changes, digitalization, globalization) have led to shifts in the kinds of skills necessary for success in the 21st century. One such skill includes collaborative problem solving (CPS), as the complexity of problems faced in the 21st century are difficult for a single individual to solve alone. In fact, among the top five skills considered “very important” for successful job performance are teamwork/collaboration and critical thinking/problem solving (Casner-Lotto and Barrington, 2006). Other sources have further identified interpersonal and communication skills as important for current and future success (National Research Council, 2008; Burrus et al., 2013; Whorton et al., 2017; McGunagle and Zizka, 2020). As students go through the education system and into the workforce, they will be expected to work with others, in face-to-face and virtual contexts, to solve complex problems, make decisions, and generate innovative ideas. These kinds of activities require individuals to have competency in skills associated with CPS.

Furthermore, decades of research have shown benefits of engaging in collaborative activities. In particular, there are positive effects of collaboration for a number of outcomes, including learning, performance, social, emotional, and psychological well-being (Lou et al., 2001; Uribe et al., 2003; Gillies, 2004; Andrews and Rapp, 2015; Jeong et al., 2019). Additionally, work has shown that problem solutions generated in groups are often better than those generated by individuals working alone (Schwartz, 1995; Dillenbourg, 1999; Barron, 2000). Such results can be attributed to division of labor afforded by groups and the opportunity to incorporate solutions from other group members with different perspectives, knowledge, and experiences (Graesser et al., 2018b). These benefits further highlight the utility of CPS in many everyday contexts such as school, the workplace, the military, and home.

What is collaborative problem solving?

Collaborative problem solving can be defined as, “the capacity of an individual to effectively engage in a process whereby two or more agents attempt to solve a problem by sharing the understanding and effort required to come to a solution and pooling their knowledge, skills, and efforts to reach that solution” (OECD, 2013, p. 6). As can be seen from the definition, there are some features that differentiate CPS from other forms of collaboration. One factor is that for CPS, the team has the goal of solving a novel problem. Team members come together to develop a plan to reach a solution to a given problem. A second factor is that the quality of the solution is transparent for the team. As they develop and implement a plan for getting from their current state to the goal state, there is opportunity to determine the extent to which the problem is solved during the course of problem solving. This is different from collaborative learning which has the goal of using collaboration to support learning of some particular content for team members without the requirement that a problem be solved. A third factor is that there is often a differentiation of roles in which team members may take on different roles (e.g., facilitator or recorder) to support solving a problem. This can differentiate CPS from collaborative decision making which involves team members having the same questions to answer or decisions to make, and often access to the same information for all team members. A fourth factor is there is typically interdependency among the team members wherein team members bring to the situation different perspectives, knowledge, and experiences that support solving a problem (Graesser et al., 2018a). This is important for many of the problems we now face in the 21st century which are often unable to be solved by a single person and require input from diverse experiences and expertise of others who bring relevant knowledge to the table.

The growing need for individuals to pool their knowledge, skills, and expertise together to solve the challenging problems of today and the general acknowledgment of the importance of CPS has motivated interest in national assessments, international assessments and curricular reform geared toward the measurement and development of CPS skills (National Research Council, 2011; OECD, 2013; Hesse et al., 2015; Care et al., 2016; Fiore et al., 2017). This interest has brought to light particular challenges with assessing an individual's competency in CPS. In the next section, we outline key challenges that make CPS assessment a relatively difficult undertaking.

Challenges with CPS assessment

The definition of CPS alone implies the need for assessment of numerous complex skills such as sharing important information and monitoring problem solving to discover an optimal solution to the task at hand. Thus, the definition in and of itself creates some obstacles for measuring how one performs on CPS tasks, as it requires students to display evidence of skills associated with both a cognitive dimension corresponding to problem solving processes and a social dimension corresponding to collaboration or teamwork processes. This makes for a diverse set of skills across a range of disciplines such as individual problem solving, linguistics, computer-supported collaborative learning, and critical thinking (Care et al., 2016). The process-oriented nature of the construct undermines the use of traditional types of assessment (e.g., multiple choice questions) (Davey et al., 2015). For example, with other domains like mathematics, one can determine a student's proficiency according to whether or not a student has correctly answered a question associated with the specific isolated concept under investigation (e.g., the concept of function). CPS is more complicated, as determining proficiency requires individuals to go through the process of interacting with others to solve a problem. The behaviors that the individuals engage in during this interaction need to allow for gathering appropriate evidence to signify an individual's CPS skills.

To accomplish the goal of assessing CPS skills, students must interact in a space that captures evidence of individual skills. Creating and administering CPS activities for individuals in face-to-face settings is an option, but can be quite expensive, time consuming, and difficult to carry out at a large scale. Difficulty with measuring interactive constructs with traditional types of tests and challenges with face-to-face administrations has led a turn to the use of digital environments which have seen a great deal of technological advancements over the years. Such environments offer opportunities for individuals to demonstrate performance around complex problems, and further afford the recording of all individuals' actions and discourse during task engagement, providing sources of evidence for CPS proficiency. However, the use of digital environments can introduce additional challenges. One challenge is associated with operationalizing CPS at the level of granularity suitable for data output from the digital environment (Kerr et al., 2016). A secondary challenge is identifying targeted skills from fine-grained log data generated during individuals' task engagement. Digital environments (e.g., games, simulations, scenario-based tasks) can log every action that each user takes thus making it difficult for analysts to determine the signal from the noise. Each action is typically at a small grain size (e.g., mouse clicks, utterances) which requires multiple levels of parsing, aggregating information to create features, and extracting the features, and there are few guiding principles for how to carry out such work (Gobert et al., 2012). Additionally, log file data are often sparse in nature, meaning that one variable or logged action may have records for many individuals whereas another action may only have few if any instances of a student behaving in a certain way. This makes it difficult to understand the generalizability of discovered student actions (Romero et al., 2009; Honey and Hilton, 2011).

These challenges have led to a number of design approaches for CPS assessment, many of which incorporate constraints on the computerized environment and thereby reduce the degrees of freedom for individuals' interaction with the task to aid in establishing traditional measurement properties such as reliability and validity (all of which require a certain amount of control over the problem space). For example, the 2015 Program for International Student Assessment's (PISA) large-scale international assessment of CPS utilized a computer simulated human-agent approach such that each human participant interacted with one, two, or three computer artificial agents as their team members rather than humans. Communication between the human participants and computer agents were carried out using a predetermined set of message options that human participants could select for each problem. This design was utilized to provide consistency and control over the interactions (OECD, 2013, 2017). Other CPS assessment work has utilized highly constrained environments in similar ways in an effort to narrow the problem space (Chung et al., 1999; Hsieh and O'Neil, 2002; Herborn et al., 2017). Some work has incorporated open chat dialogue among human collaborators, but often analyses have treated the chat messages as simply another action type without considering the content of the chat messages (Care and Griffin, 2014; Adams et al., 2015) or the problem has been constrained so that little variation can occur for the kinds of actions and communication in which individuals engage (Hao et al., 2015; Liu et al., 2015). All of these design decisions, while chosen to deal with various constraints (e.g., limited capabilities for natural language processing), do not allow for detailed measurement of both the actions and discourse of individuals at a fine grain size (Andrews-Todd and Forsyth, 2020). In the next section, we describe one approach developed at Educational Testing Service that was designed to address many of the aforementioned challenges for CPS assessment and to support measurement of CPS skills when the previously mentioned constraints are undesirable.

In-task assessment framework

The in-task assessment framework (I-TAF) was developed to provide guiding principles to support the development of assessments for complex constructs in digital environments (Kerr et al., 2016). I-TAF is informed by evidence-centered design (ECD) (Mislevy et al., 2003), and specifically serves as an approach to instantiate the conceptual assessment framework layer of ECD (i.e., the

student model, task model, evidence model) when evaluating complex constructs in digital environments where the grain size of the data is small. The student model represents what is being measured and includes defining the variables that make up the targeted knowledge, skills, and abilities. The task model addresses where we are measuring the targeted skills and includes the features or affordances available in a task that would be needed to attain evidence of targeted skills. The evidence model concerns how we will measure the targeted skills and includes how we will identify features corresponding to what individuals do and how we will use that information to make inferences about what individuals know and can do. I-TAF provides principles for carrying out each of these models, particularly how one might operationalize a construct, extract evidence of the construct, and link the evidence back to the construct of interest when dealing with low-level log data rather than traditional item response data (Andrews-Todd and Forsyth, 2020).

With standard item response data, variables for the student model are associated with whether a person answers a question correctly or incorrectly; however, with digital environments and process-oriented constructs like CPS, more complex processes are needed to define variables associated with the targeted constructs. In particular, the construct needs to be operationalized in terms of behaviors. For this purpose, I-TAF advocates for the use of an ontology (similar to a concept map) which lays out the construct in a principled way and does so at the level of granularity of data output from a targeted task environment. Specifically, an ontology provides a graphical representation in which high- and low-level concepts are represented by nodes and relationships between those concepts are represented by links (an example of a portion of an ontology is given in Fig. 2 and discussed in the [Example application for operationalizing CPS](#) section). This representation provides a unified definition and shared vocabulary for a domain that can make explicit the presumed dependencies among concepts and skills and also provide a format that can be communicated among humans and computational systems. Because data on complex constructs in digital environments are often process-oriented rather than the selection of a correct or incorrect answer choice, nodes in the ontology should not only include concepts and skills associated with a targeted construct or domain, but also an additional layer that provides behaviors or actions one can take to demonstrate evidence of targeted concepts and skills (e.g., “take measurement” or “ask expert”). A further layer of the ontology introduces tactics that are available in a targeted task environment for carrying out strategies in the ontology. This is important since tactics for carrying out a given strategy can differ based on affordances available in a task. For example, one task may have the option to visit the library to carry out the “ask expert” strategy while another task may afford speaking to a non-playable character. With this, the ontology provides key evidence elements to be identified in the data to make inferences about individuals (Kerr et al., 2016).

I-TAF also provides principles for identifying features using combined top-down and bottom-up approaches. For example, human (e.g., qualitative coding) or machine (e.g., natural language processing) driven approaches can be used to identify features in the data that were outlined in the ontology. Any unattributed actions found in the data can utilize data mining or machine learning approaches to aggregate individual actions into meaningful units of behavior. Extracted behaviors can then be aggregated into variables with processes such as counting the number of instances the feature is observed or calculating the proportion of instances of a correct action. Such variables can then serve as inputs into different measurement or statistical models. The development of the ontology also informs task design, as it can make salient affordances that are (or are not) available in a task to facilitate its measurement properties. For example, if a strategy is deemed important and included in the ontology, but there are no affordances available in the task for carrying out the strategy, then changes to the task design are needed to accommodate the desired strategy. For additional insights related to CPS task design, see Hao et al. (2019) and Coiro et al. (2018). For more detailed information about I-TAF, see Andrews-Todd and Kerr (2019) and Kerr et al. (2016). In the sections to follow, we highlight some examples of how to apply some principles of I-TAF to deal with aforementioned challenges associated with CPS assessment work.

Context for example applications

To describe how to address CPS assessment challenges with I-TAF, we will set examples in the context of a task environment called the Three-Resistor Activity (Horwitz et al., 2017). The Three-Resistor Activity is a collaborative simulation-based task on electronics concepts associated with current, resistance, and voltage. In the task, students work in groups of three, each on a separate computer that runs a simulation of a portion of an electronics circuit. The three simulations are linked to form a series circuit. On each computer screen, students have access to a digital multimeter (DMM) to take measurements, probes from the DMM that can attach to a resistor, a resistor where students can view and change the circuit’s resistance, a zoom button to view other teammates’ boards, a calculator to perform calculations, a text-based chat window to communicate with teammates, and submit buttons to submit work (see Fig. 1 for a screenshot of the task interface).

In the Three-Resistor Activity, students are tasked with setting their resistors so that the voltage across them reaches a specified goal voltage. With the circuits connected in series, any change that one person makes will affect readings on other students’ boards, thus making it important for students to work together to coordinate how to reach their goal voltage values. The task includes four levels of increasing difficulty, with higher levels requiring students to not only reach their goal voltage values, but also figure out the unknown resistance and supply voltage of a fourth circuit in the series. As students interact in the task, all of their relevant actions (e.g., measurements, calculations, resistor changes, chat messages, submissions) are captured and logged to a database.

Example application for operationalizing CPS

In an NSF-funded grant (DUE-1535224), researchers utilized I-TAF to support the operationalization of CPS. Specifically, they developed a CPS ontology for use in assessing CPS skills for undergraduate students in engineering, electronics, and physics courses who completed the Three-Resistor Activity. To develop the CPS ontology, they first conducted an extensive literature review to explore existing frameworks on relevant constructs and work in related areas such as individual problem solving, computer-supported collaborative learning, linguistics, and organizational psychology. This review yielded a list of candidate concepts and skills for the ontology. Subject matter experts (SME's) then reviewed the list and determined relationships between agreed-upon components and definitions. Any disagreements among the SME's were resolved through discussion. This process yielded a construct definition for CPS with concepts or skills associated with CPS and the relationship between them. As noted in the previous section on the "In-Task Assessment Framework," additional steps in developing an I-TAF ontology includes incorporating additional layers to specify the construct at multiple layers of granularity to appropriately reason up from low level behaviors in the digital environments (e.g., button clicks) to higher level proficiencies.

The additional layers in the ontology operationalize CPS in terms of behaviors or strategies and then the tactics or affordances available in a task to carry out the strategies. For these additional layers, team members came together to determine what kinds of behaviors a student would need to show to demonstrate evidence of the skills in the construct definition portion of the ontology. For example, for the "executing" skill, one sub-skill is "enact strategies" and an example behavior for this skill was "take action to carry out plan" with the tactics or affordances available in the Three-Resistor activity to carry out these behaviors being "calculate," "modify," and "measure." As another example, for the "negotiating" skill, the sub-skills are "agree," "disagree," and "resolve conflict" and corresponding example behaviors or strategies are "make disagreement statement," "make agree statement," and "propose alternate" with tactics or affordances available in the Three-Resistor Activity to carry out these behaviors being the "chat" function. A screenshot of a portion of the CPS ontology can be found in Fig. 2. For additional information on how the CPS ontology was created, see Andrews-Todd and Kerr (2019).

Altogether, the CPS ontology includes nine high level skills divided into a social (teamwork, collaboration) and a cognitive (problem solving, taskwork) dimension. In the social dimension, the four skills include maintaining communication, sharing information, establishing shared understanding and negotiating. Maintaining communication includes the subskills rapport

Fig. 2 Portion of the CPS ontology.

building communication (e.g., greeting teammates, praising teammates), off-topic communication (e.g., discussing what was had for breakfast), and inappropriate communication (e.g., degrading teammates). Sharing information includes the sub-skills sharing one's own information (e.g., sharing one's goal voltage value), sharing task or resource information (e.g., sharing where the zoom button is located), and sharing the state of one's own understanding (e.g., metacognitive statements such as "I don't know"). Establishing shared understanding includes subskills associated with requesting information from teammates (e.g., "what is your resistance value?"), providing statements to indicate comprehension of teammates' communication (e.g., "ok," "I got you," or requests for clarification), and communication to make repairs when misunderstandings arise. Negotiating includes the sub-skills expressing agreement (e.g., "yes," or "you're right"), expressing disagreement (e.g., "that's not right"), and resolving conflicts.

In the cognitive dimension, the five skills include exploring and understanding, representing and formulating, planning, monitoring and executing. Exploring and understanding includes sub-skills associated with exploring the problem space and trying to understand the problem. Representing and formulating includes sub-skills for representing the problem (e.g., "this is a series circuit") and formulating hypotheses. Planning includes subskills for setting goals, managing resources (e.g., establishing roles), and developing strategies for solving the problem. Executing includes sub-skills for enacting strategies (e.g., changing to a resistance value suggested by a teammate), suggesting actions for teammates to take to carry out a plan (e.g., "adjust your resistor to 300 ohms"), and reporting own actions to others for carrying out a plan (e.g., "I am going to set mine higher"). Monitoring includes sub-skills for monitoring success toward solving the problem (e.g., "I've got my goal voltage") and monitoring the organization of the team (e.g., "Let's get a move on Hawk"). A list of the high level CPS skills and their definitions can be found in [Table 1](#).

To test the generalizability of the CPS ontology, researchers have applied it in multiple other projects with various contexts and those applications showed the CPS ontology was suitable across different age groups, domains, group compositions, and communication modalities. One example is an IES-funded grant (#R305A170432) which included CPS assessment for middle and high school aged students working in pairs to complete two tasks. One task was an online mathematics task on linear function concepts and argumentation called the T-Shirt Math Task ([Andrews-Todd et al., 2019](#)) in which students worked to determine which of three t-shirt companies was the best choice to purchase t-shirts for their class. The second task was an open-ended physics educational game called Physics Playground ([Shute et al., 2013](#)) in which students, across multiple task levels, had the goal of drawing various objects (e.g., ramp, springboard) to make a ball hit a balloon target. In both tasks, students had multiple modalities available for

Table 1 CPS skills and definitions.

<i>Dimension/skills</i>	<i>Definitions</i>
Social dimension	
Maintaining communication	Content irrelevant social-oriented communication (off topic, rapport building).
Sharing information	Sharing content relevant information (status, role, task information).
Establishing shared understanding	Communication to get on same page as teammates and ensure understanding/comprehension of teammates' contributions.
Negotiating	Communication to express agreement, disagreement, and resolve conflicts that arise.
Cognitive dimension	
Exploring and understanding	Actions to build a mental representation of components of the problem
Representing and formulating	Communication to represent the problem or develop hypotheses.
Planning	Communication to set goals, manage resources, or develop strategies for solving the problem.
Executing	Actions to carry out a strategy or communication to suggest actions for teammates or report own actions.
Monitoring	Actions to check the status of teammates or communication to state task progress and determine whether teammates are doing as they should.

communication, including video and audio channels. For this work, the CPS ontology was modified at only the tactic level to align the ontology with the affordances available in the project tasks. For example, for the executing skill which has the behavior of “take action to carry out plan,” the tactics in the T-Shirt Math Task for carrying out this behavior would be to “type” a response or “submit” an answer choice rather than the affordances of “measure,” “modify,” and “calculate” from the Three-Resistor Activity. In situations in which targeted tasks have similar affordances, no modifications are needed at the tactic layer of the ontology.

Example applications for evidence identification and accumulation for CPS skills

As previously mentioned, discovering targeted behaviors within fine-grained log data aligning to the skills of complex constructs such as CPS can be challenging. With the Three-Resistor Activity, features were extracted from the log data that were identified a priori from the CPS ontology. In the given context, the majority of the data were chat data so qualitative coding was used to support feature extraction. The CPS ontology was used to create a rubric for the human raters. To do this, the nodes and links corresponding to the CPS skills in the ontology were transformed into written protocols that included the high level CPS skills, sub-skills within each skill, definitions associated with each skill, example behaviors from log data that provide evidence of each skill, and action types corresponding to each skill (e.g., chat, measurement, calculation). The raters were trained on the rubric using a subset of log data from the Three-Resistor Activity where they would identify each row corresponding to a student action or discourse as evidence of one CPS skill. Two raters then coded 20% of the data to establish inter-rater reliability. Any disagreements that arose for raters were discussed for the purpose of coming to a common understanding of the rubric interpretation. The remaining data were divided among the raters to code independently. Raters have demonstrated good agreement across two data collections with this CPS rubric (Kappa = 0.84 and 0.93, respectively) (Andrews-Todd and Forsyth, 2020; Forsyth et al., 2020).

Note that machine-driven approaches for feature extraction are also applicable, and can potentially save time and money. For example, in the previously mentioned IES-funded CPS assessment work, natural language processing (NLP) algorithms were used to automatically analyze the CPS discourse. Specifically, Random Forest Classifiers, a deep transfer learning approach called the Bidirectional Encoder Representations from Transformers (BERT) model, and a version of the BERT model that incorporates contextual utterances (i.e., previous and subsequent utterances) have been explored, with the latter performing best in predicting CPS skills within two tasks focused on math and physics (Pugh et al., 2021). Recent work has also applied machine learning methods, specifically a k-nearest neighbors classifier, to automate the classification of CPS skills from the CPS ontology for data from the Three-Resistor Activity. This method showed strong agreement with human annotations (Flor and Andrews-Todd, in press). Additional work has also explored various NLP approaches for automating the identification of CPS skills with promising results (e.g., Flor et al., 2016; Hao et al., 2017; Pugh et al., 2022; Stewart et al., 2019). Once features are extracted, analyses can be carried out with the features to accumulate evidence and report high level proficiencies associated with CPS for individuals. In the following subsections, we provide some examples for how this has been carried out in prior work on the Three-Resistor Activity to show descriptions of learner behaviors and profiles to characterize individuals as types of collaborative problem solvers.

Descriptions of learner behaviors

One strategy for aggregating evidence about individuals' CPS skills is to provide simple descriptions of behaviors. Methods for describing learner behaviors can be approaches such as generating frequencies or counts associated with the number of times an individual displayed targeted CPS skills as evidenced by the extracted features or proportions that take into account all CPS behaviors displayed or totals from a population of interest (e.g., other students from the class) (Zapata-Rivera et al., 2021). With this strategy, we can examine the number of displayed behaviors for each skill not only to understand what the students did but to

also ensure that the behaviors from the CPS ontology were indeed exhibited. This is important because if individuals are not displaying behaviors associated with important CPS skills, we may either need to modify the environment to better provide opportunities for individuals to display targeted CPS skills, consider the possibility that a certain skill cannot be measured with the current task, or infer that individuals may not possess the necessary level of CPS proficiency to display targeted CPS behaviors when given the opportunity. Across two different datasets for the Three-Resistor Activity, students did indeed display the targeted CPS skills from the CPS ontology, but variance did exist. Specifically, students displayed a high level of executing actions whereas representing and formulating and negotiation were displayed less frequently (Andrews-Todd and Forsyth, 2020). Other work has similarly applied such strategies for characterizing CPS behaviors through counts of descriptive behaviors (e.g., Scoular et al., 2017). These types of insights can inform inputs for creating profiles of types of collaborative problem solvers as shown in the next subsection.

Profiles

Another strategy for aggregating evidence about individuals' CPS skills is a profile approach which can provide a way to characterize learner behaviors at a high level. Andrews-Todd and Forsyth have used two different techniques to create learner profiles, including comparing proportional values of displayed skills on social and cognitive CPS dimensions via median splits (Andrews-Todd and Forsyth, 2020) and hierarchical clustering techniques (Andrews-Todd et al., 2018; Forsyth et al., 2020), both of which build on the frequency strategy described previously. In the first technique, students were categorized based on aggregate frequencies of CPS skills corresponding to the high level CPS skills. The frequencies of CPS skills for each dimension (i.e., social vs. cognitive) were ranked and split into roughly 2 equal groups of high and low display of CPS skills for each dimension, respectively. After calculating these for each dimension independently, four groups were then created, corresponding to a 2×2 social and cognitive dimension matrix (i.e., high cognitive with high social, high cognitive with low social, low cognitive with high social, and low cognitive with low social). Aligning with expectations, students in the low cognitive/low social profile tended to underperform relative to students in other profiles on the Three-Resistor Activity (Andrews-Todd and Forsyth, 2020).

In the second technique, an exploratory clustering method was conducted with the CPS skill frequencies that were generated from qualitative coding of the Three-Resistor Activity log data. A four cluster solution was utilized, as these clusters aligned with interpretations from relevant theory and literature associated with collaboration, cognitive, and communication sciences. The four clusters were labeled as *Chatty Doers*, *Social Loafers*, *Active Collaborators*, and *Group Organizers*. Chatty Doers included individuals who had a high level of executing actions (e.g., resistor changes, calculations) and content irrelevant social communication (maintaining communication). Social Loafers were students that displayed below average frequencies on all CPS skills whereas Active Collaborators displayed above average frequencies on the social and cognitive CPS skills relative to the other profiles. Group Organizers tended to display behaviors associated with organizing the problem and the group (e.g., monitoring actions, representing and formulating) (Andrews-Todd et al., 2018). Similar cluster analyses were run on another dataset from the Three-Resistor Activity and yielded four clusters, two of which were different from the first cluster analysis. The two new clusters were *Super Socials* who displayed high levels of social CPS skills relative to other clusters, but did not demonstrate many important cognitive CPS behaviors (other than representing and formulating) and *Low Collaborators* who communicated little with teammates, but did carry out a high level of executing actions (e.g., resistor changes, measurements) (Forsyth et al., 2020). It is important to note that only profiles that aligned to theory or the ontology were accepted as a theoretically-grounded data mining technique was employed to ensure the meaningfulness of the findings (Forsyth et al., 2014). Each of the profiles were validated with external measures and results were in expected directions (e.g., Active Collaborators tended to perform better than Social Loafers). Other work has similarly utilized profile methods with CPS data and has also yielded promising results (e.g., Herborn et al., 2017; Coiro et al., 2019; Dowell et al., 2020).

Discussion and ongoing work

In recent years, more attention has been given to the assessment of CPS skills through interactive tasks, particularly with international assessments such as PISA (OECD, 2013) and the Assessment and Teaching of 21st Century Skills (ATC21S) (Griffin et al., 2012) and national assessments such as the National Assessment of Educational Progress (NAEP) (Fiore et al., 2017). Such attention, motivated by new challenges in today's world that require competency in CPS, has led to advancements that seek to deal with a number of challenges associated with assessment of complex constructs like CPS. In this article, we describe one such advancement, the I-TAF framework, that has utility in providing guiding principles for assessing complex constructs in digital environments. Specifically, we describe and provide examples for how I-TAF can be used to support the operationalization of CPS at a level of grain size appropriate for data from digital environments. We further provide examples for how I-TAF can support evidence identification or extraction of features related to targeted CPS skills, and evidence accumulation, including how to aggregate information about individuals' CPS behaviors to make inferences about higher level CPS proficiencies. The use of such an approach that incorporates a competency model a priori (considered top-down) along with data-driven (or bottom-up) approaches is important when considering a complex construct such as CPS and the thousands of rows of log data produced by student interaction in digital environments. Using purely bottom-up approaches can present challenges for linking features or behaviors to constructs in a targeted domain. Specifically, features without theoretical grounding can produce spurious correlations to skills that are not well aligned with the targeted construct. Purely top-down approaches can also present challenges such as not allowing for the emergence or identification of new features or behaviors that may be important to capture.

There still remain some areas in the space of CPS work that were not addressed in the current article. One area includes exploration of the generalizability of individuals' CPS skills from one context to the next. This is an area that still requires further investigation, though preliminary work suggests mixed results. For example, [Martin-Raugh et al. \(2020\)](#) found evidence for the generalizability of negotiation skills across tasks. Alternatively, [Andrews-Todd et al. \(2021\)](#) found that 37% of participants demonstrated behaviors associated with the same CPS profile across a math and physics task; however, only 10% of participants showed change from high levels of CPS skills to low levels of CPS skills (or vice versa) from one task to the next. The generalizability of CPS skills across contexts likely depends on a number of factors such as the type of task being completed, the composition of the group, and the communication modality.

A second area includes development of quantitative scoring strategies for CPS assessment. In the current article, we discuss strategies for aggregating information about individuals to characterize their CPS behaviors using more descriptive means. Such strategies can support providing meaningful information to learners, teachers, and other stakeholders that can be used to support learning interventions to target identified gaps. These characterizations of learner behaviors require replication across numerous domains and environments to ensure validity, a process that is a part of ongoing work. However, some work has also sought to instead create ways to provide quantitative scores for individuals regarding their CPS skill (e.g., the PISA 2015 CPS assessment). Some of this work has done so as to accommodate various constraints related to issues such as budget, time, particular requirements associated with psychometric quality, or technological limitations. One challenge with such strategies is that CPS is often mapped to a unidimensional scale with approaches such as item response theory (IRT) models; however, CPS is a multidimensional construct. Using methods that assume unidimensionality oversimplifies the richness of CPS and information gathered from corresponding tasks and can also compromise the validity of the assessment ([Hao et al., 2019](#)). There is ongoing work that seeks to develop and employ statistical and psychometric models that take into account the multidimensional nature of CPS. Example models include network analyses, Andersen/Rasch multivariate IRT models, and Bayesian Knowledge Tracing (e.g., [Andrews et al., 2017](#); [He et al., 2017](#); [Polyak et al., 2017](#); [Zhu et al., 2020](#)).

A third area that builds on the assessment work being done for CPS is learning interventions and training materials that target development of CPS skills. With acknowledgment of the importance of CPS for success in today's world, it is important to not only be able to inform individuals about their CPS proficiency, but also to facilitate improvement in CPS skills that are needed. Unfortunately, little work has been put forth to tackle training to help support development of CPS skills for individuals in colleges, industry, and the military, particularly work that is theoretically driven ([Fiore et al., 2018](#); [Graesser et al., 2018a](#)), though work in the computer-supported collaborative learning literature has explored supports for collaborative learning such as adaptive feedback (e.g., [Soller et al., 2005](#); [Walker et al., 2009](#); [Hassan et al., 2019](#)). Andrews-Todd and her colleagues have begun such work through different avenues such as developing and piloting online training modules for CPS skills for higher education populations and conducting research to better understand how to provide real-time feedback to individuals in groups solving problems in computerized environments focusing on types of feedback and timing of delivery. Additional future work includes providing real-time reports in the form of dashboards to teachers and students for intervention during collaborative problem solving. Presenting dashboards that are intuitive to users requires its own line of research, including exploring the needs, knowledge, and attitudes of users, the usability of the dashboard itself, how to best present data in a dashboard, and how to support interpretation of information for decision making ([Zapata-Rivera and Katz, 2014](#); [Kannan et al., 2018](#); [Zapata-Rivera et al., 2018](#)).

Although challenges still remain, significant progress in defining and measuring CPS skills in digital assessments has been made. This is important as CPS is becoming increasingly more valued in the age of technology. Students will need to be able to demonstrate proficiency in working in multidisciplinary teams to solve problems. Developing and implementing CPS assessments and supports for improving CPS skills will remain of strong interest for researchers for years to come.

Introduction

Conversation-based assessments (CBAs) offer a way to engage students in computer-based dialogs aimed at gathering evidence of what they know or can do. Advances in natural language understanding, dialog systems, and interaction with artificial agents make it possible to design and implement guided natural language conversations that can be used to collect evidence of students' knowledge, skills, and other attributes (KSAs). These CBAs can be used in conjunction with other types of tasks and can be embedded in scenario-based tasks, simulations, and other technology rich tasks.

In this article, we: (a) review relevant work in the area of dialog systems; (b) describe how CBAs were designed to assess complex 21st century constructs such as science inquiry and English language communication skills, elaborate on development and scoring issues, and provide examples of research on the development and evaluation of CBA tasks; (c) connect this work to work on designing and evaluating personalized, “caring” assessments, which extend the scope of the student model to include cognitive and non-cognitive aspects of the student as well as aspects of the learning context to create assessment experiences that provide valued evidence of student performance while considering students' learning needs (Zapata-Rivera, 2017), and elaborate on the connection of this work with Universal Design for Learning (UDL; CAST, 2018) as a framework to support the varying needs of diverse learners; (d) discuss work on exploring student emotions and individual differences in CBAs; (e) report on current challenges and areas for future work elicited from experts in dialog systems; and (f) discuss our view of challenges and future work in the area of CBAs. In addition, we provide an annotated list of resources in [Appendix A](#) for new students and researchers compiled from experts in the field.

Dialog systems

Conversation-based systems for learning and assessment provide opportunities for students to discuss various topics with artificial agents—embodied characters or “talking heads”—that can respond to students in real time. These types of educational environments began emerging in the 21st century (Biswas et al., 2010; Gholson et al., 2009; McNamara et al., 2006; Olney et al., 2012; Ward et al., 2013). These systems cover academic topics ranging from physics, biology, scientific reasoning, and computer literacy to constructs such as self-regulation and meta-cognition (see Graesser, 2016 for review).

Dialog systems often make use of artificial virtual pedagogical agents (Johnson et al., 2000; Johnson and Lester, 2016)—virtual characters or avatars designed to engage the learner and provide a simulated social context in which the conversational interactions occur with the virtual agent, with the aim of supporting students' learning. Virtual agents promote deep learning and motivation through adaptive dialogic interactions (Atkinson, 2002; Baylor and Kim, 2005; Moreno et al., 2001). Conversational agents can convey information, pose questions, provide feedback, guide attention, and serve as a virtual teammate for the human learner (Johnson et al., 2000; Johnson and Lester, 2016). Agents' features may vary in terms of their epistemic roles or personas (e.g., knowledgeable expert or supportive motivator; Baylor and Kim, 2005; Baylor and Ryu, 2003), the quality of the language used such as formality or politeness (e.g., Wang and Johnson, 2008; Li and Graesser, 2017, 2021), whether they communicate via text, voiced audio, or some combination (Johnson and Lester, 2016; Mayer, 2005), among others (see Schroeder et al., 2013).

Perhaps one of the better-known systems that has repeatedly shown high learning gains across two decades is AutoTutor, deployed to middle-schoolers and college students. AutoTutor teaches multiple topics in STEM areas and has shown effect sizes

ranging from 0.6 to 2.0 which is comparable to human tutors (for a review, see [Graesser, 2016](#)). This is not surprising as AutoTutor was created based on analysis of expert tutors' and students' conversations ([Graesser and Person, 1994](#)). The dialogic framework uses scaffolding moves which are positively correlated with learning in AutoTutor ([Jackson and Graesser, 2006](#)). The positive relationship to learning may be explained by Chi's ICAP (Interactive, Constructive, Active, Passive) model of learning which predicts that active interaction aids learning more so than passive interaction (for more information see [Chi, 2009](#)). (Note: Additional constructs may also aid in learning with this framework, for more information [Forsyth et al., 2020b](#)). The primary scaffolding moves correspond to a framework called Expectation-Misconception tailored dialog. The main idea of this framework is that a student is asked a question with an expected correct answer and known misconceptions that are identified and implemented within the system a priori. Scaffolding techniques are then used to adaptively help the student articulate these expected answers. Such scaffolding moves include hints (broad clues), prompts (requiring single word or phrase answers), misconceptions correction, and assertions. A mixture of two different algorithms (Regular Expressions and Latent Semantic Analysis) are used to analyze the human input. Specifically, regular expressions are implemented to capture a specific word or phrase ([Jurafsky and Martin, 2008](#)). Latent Semantic Analysis (LSA) is a geometric pattern matching algorithm that allows the human input to be interpreted in context (see [Landauer et al., 2007](#)). Together, the evaluation of human responses made by these two algorithms are highly correlated with expert human raters; that is, the automated raters and expert human raters have moderate/high inter-rater reliability ([Cai et al., 2011](#)), making possible the illusion of intelligence when artificial agents provide appropriate responses. After the human input is analyzed and categorized, the dialog manager or dialog engine is used to determine the appropriate response (e.g., what should be said? And who should say it?).

There have been several AutoTutor derivatives based on this conversational framework, including OperationARA ([Millis et al., 2011](#); [Forsyth et al., 2014](#)). OperationARA is a serious game designed to teach research methodology to college students and could potentially also be well-suited for high-school students. Students learn about twelve topics of research methodology while engaging with two or more virtual agents across three different teaching modules. The students begin by learning the basic shallow information (such as vocabulary) and then progress to applying information and finally generating questions (three levels of student interaction that research suggests will require students to have a progressively deeper understanding of the content; [Forsyth et al., 2013, 2020b](#)).

The conversational structure of OperationARA is based on the AutoTutor framework but with the extension of one or more additional artificial agents. The resulting multi-party conversations are referred to as "trialogues" ([Graesser et al., 2017](#)). Within ARA, trialogues increase the adaptivity of the conversation so that students receive personalized instruction based on their current level of knowledge. Specifically, students with low prior knowledge may benefit the most from simply observing two artificial agents, an expert and a student agent, interact (vicarious learning mode; [Driscoll et al., 2003](#)). Conversely, students with high prior knowledge may benefit more from teaching another agent, referred to as the teachable agent mode. The intermediate students receive the regular AutoTutor framework. In addition to providing this level of personalization, trialogues create more assessment possibilities as novel dialogic conversations are possible.

Another application of dialog-based approaches involves the assessment of complex constructs such as collaborative problem solving (CPS; [Andrews-Todd and Forsyth, 2020, 2022](#); [Graesser et al., 2017a,b, 2018](#); [Herborn et al., 2020](#); [Rosé et al., 2017](#)). In fact, many 21st century skills such as CPS lend themselves to be assessed using interactive tasks, as assessing CPS in a simulated environment is necessary to capture evidence of both cognitive and social skills ([Andrews-Todd and Forsyth, 2020](#); [Coiro et al., 2019](#)). For example, PISA has implemented dialog-based tasks to assess CPS on a world-wide scale using a simulated environment ([Csapo et al., 2012](#)).

The simulated environment implemented in PISA for this purpose used artificial agents to guide students in highly constrained, text-based, menu-driven conversations. This environment includes some of the characteristics of CBAs, but it is designed for high-stakes assessment. Specifically, rather than the mixed-initiative free flowing conversations implemented in other tutorial systems (e.g., AutoTutor; for review, see [Graesser, 2016](#); [GuruTutor](#); [Olney et al., 2012](#)) as well as other adaptive modeling for student interactions that provide students the needed level of support based on their current knowledge level to aid them in solving physics problems (e.g., [Katz et al., 2021](#)), students were given forced choice options to respond to the agents. Although, this design choice can be used to elicit clear evidence of particular aspects of CPS skills ([OECD, 2013](#)), it limits the types of conversations that could be observed in real-world contexts. Researchers have continued to explore methods of analysis to measure CPS in less constrained environments to improve assessment of this construct in lower-stakes situations ([Forsyth et al., 2020a](#)). In these formative contexts, it is possible to integrate more naturalistic conversations to elicit fine-grained evidence of student KSAs. Specifically, we can capture information about students with natural language conversations in the context of conversation-based assessments.

Conversation-based assessments

Conversation-based assessments (CBAs) result from the need to gather additional evidence of the decisions students make on performance-based assessments such as computer-based scenarios, simulations, or other forms of technology rich tasks ([Zapata-Rivera et al., 2013](#)). CBAs involve the use of artificial agents that are designed to engage students in conversations about the nature of their decisions in the assessment environment ([Zapata-Rivera et al., 2015a,b](#)). CBAs build on research results in areas such as dialog systems ([Adamson et al., 2014](#); [Graesser et al., 2001](#); [Millis et al., 2011](#)), artificial virtual agents ([Johnson and Lester, 2016](#)), and technology enhanced assessments ([Bennett et al., 2007](#); [Clarke-Midura et al., 2011](#); [Quellmalz et al., 2011](#)).

CBAs have been used to gather evidence of middle-school students' KSAs that may be difficult to obtain using traditional assessment approaches. CBAs are useful for eliciting additional explanatory evidence for a variety of KSAs. For example, guided conversations or dialogs with artificial agents can be used to assess 21st century skills such as argumentation, science inquiry, critical thinking, and collaborative problem solving. CBAs can also be used to assess communication skills (e.g., English language skills such as reading, writing, listening, and speaking). CBAs can be used in conjunction with other item types in a variety of assessment situations, including simulation-based, scenario-based, and game-based assessments (So et al., 2015; Song et al., 2014; Zapata-Rivera et al., 2014).

CBAs can be used to gather evidence of students' explanations about decisions that they make in technology rich environments (e.g., Why were particular pieces of data used to support a prediction? Why was a particular combination of parameters selected to run the simulation?). Because they leverage an adaptive dialogic framework similar to the one previously described for the Auto-Tutor system` (see Zapata-Rivera et al., 2015a), CBAs can provide students with multiple opportunities to elaborate on their responses depending on the quality and content of those responses (e.g., rephrasing the question and asking the student to provide additional information after receiving an initial response that is incomplete or irrelevant), thus presenting students with a more dynamic, personalized assessment experience.

Conversations with artificial agents can be considered as an interactive constructed response item type that allows for dynamic exchanges of information about target constructs. CBAs can be used to create interactive, yet open assessment situations for students to demonstrate what they know or can do. Compared to other item types, CBAs are characterized by high levels of openness and interactivity, including the potential for students to take different conversational paths, or to introduce branching at key points based on students' interactions within the environment. By attaching CBA to other item types (e.g., responses to a MC question or interactions within a simulation), it is possible to create enhanced or hybrid items that provide opportunities for exploring the cognitive processes and strategies the student is demonstrating (Jackson and Zapata-Rivera, 2017). Taken together, these features make CBAs a suitable environment for exploring questions around personalized assessment and learning.

In the next section, we describe aspects of the development of CBA prototypes as well as some results of evaluation efforts.

CBA development and scoring

The development process of CBAs is iterative and follows the principles of evidence-centered design (Mislevy et al., 2003; Yin and Mislevy, 2022), a principled approach to assessment design that focuses on the evidence-based argument structure connecting tasks to the target constructs.

The CBA development process takes into account the context(s) where intended conversations can take place, the construct(s) that are intended to be measured, and conversation structure and adaptivity issues such as conversation openings, main questions, conversation moves/patterns used to follow-up on student responses, role of artificial agents (e.g., teacher and/or peer, who asks questions and provides feedback, type of feedback provided), initial scoring rules (e.g., specifying responses or response sequences that earn full or partial credit), task sequencing, and conversation closings. These components are represented in a conversation space diagram. This structure is converted into (a) a conversation script used by a dialog engine to manage the conversation (Zapata-Rivera et al., 2015a) and (b) scoring rules associated with each path in the conversation space diagram.

A key aspect of the CBA development process is to carefully design the interactions (e.g., questions and feedback) to address the constructs and reduce the complexity of the conversation space. Response categories are used to deal with a variety of student responses and to respond following a limited number of pre-defined paths corresponding to those categories. These branching conversations are refined based on expert input and student data. Automated testing tools and crowdsourcing have been used to speed up the development process of conversation elements such as regular expressions and language models (Zapata-Rivera et al., 2015).

Scoring approaches used in the development of CBAs include: (a) assigning initial path-based scores based on expert judgment; (b) revising initial scoring rules based on qualitative analyses of student responses; and (c) scoring produced automatically by the dialog engine based on natural language processing techniques such as LSA and regular expressions, which match student responses to expected correct responses throughout the conversation.

Performance on CBA prototypes is determined by aggregating evidence from different types of items including multiple-choice questions, constructed responses and conversations with artificial agents into a comprehensive total score. In situations where multiple constructs are measured, we compute a single measure of performance per each construct.

CBAs are evaluated by conducting small-scale studies such as usability studies, cognitive labs, and path validation studies (used to explore how the system responds to student utterances), and large-scale studies examining issues like the effects of different types of questions or characters on CBA performance, the types of emotions participants experience in these environments, how the type of evidence gathered through CBAs compares to external measures, and how subgroups of students (e.g., English language learners) interact with CBAs. CBAs provide a rich amount of data and offer researchers with an opportunity to explore issues surrounding the design and evaluation of advanced measurement modeling and scoring approaches that are appropriate for these kinds of tasks.

CBA examples

Several CBA prototypes have been designed to assess skills such as science inquiry (Zapata-Rivera et al., 2014; Liu et al., 2016), mathematical reasoning (Cayton-Hodges et al., 2015), formulating and justifying arguments (Song et al., 2014), collaborative problem solving (Hao et al., 2015); and English language skills for English learners (So et al., 2015; Evanini et al., 2014). An additional prototype assessed both English language and mathematics skills in an integrated environment (ELLA-Math; Lopez et al., 2021). The development of these prototypes involved an interdisciplinary team with expertise in areas such as dialog systems, assessment development, cognitive science, human-computer interaction, game design, and psychometrics.

These CBA prototypes make use of a variety of question types (e.g., multiple-choice, inline choice, constructed response) in addition to conversations with artificial agents. The type of evidence gathered using CBAs compared to other types of tasks has been analyzed (Forsyth et al., 2018; Liu et al., 2016; Zapata-Rivera et al., 2016). Results of these studies have shown that English language learners interacting with CBAs produce relevant responses comparable to those that are generated in human-to-human communication (Forsyth et al., 2018) and that CBAs can be used to collect additional evidence of targeted constructs (e.g., additional dimensions of the constructs), compared to the evidence collected using other types of tasks (Liu et al., 2016; Zapata-Rivera et al., 2016). Thus, it is possible to develop isomorphic CBA prototypes (i.e., tasks with similar underlying structure, but with different surface features in terms of topic and content) to collect similar types of evidence in different scenario contexts with the same underlying skills, which has implications improving scalability by facilitating repurpose of conversation elements such as dialog scripts and other components of the environment (Liu et al., 2016; Zapata-Rivera et al., 2015a).

CBA prototypes have been implemented using various levels of fidelity, ranging from text-based graphical interfaces with static images representing the agents to interactive immersive environments with animated, embodied agents. Fig. 1 shows a screenshot of the ELLA-Math prototype, which was designed to assess English language skills and math content knowledge of middle school English learners. In this prototype, the student works with two artificial fellow students on solving small-group activities. Students take turns reading the questions and engaging in conversations aimed at supporting understanding of the questions and scaffolding the math concepts required to solve each task. The prototype makes use of open response and multiple-choice tasks. Conversations are triggered based on what the student types (open response task) or selects (multiple-choice tasks). Multiple-choice tasks include choices such as “I do not understand ...” which triggers conversations aimed at clarifying the question. Response categories handled by CBA prototypes usually include correct, partially correct, incorrect, irrelevant, meta-communicative (e.g., “What did you say?” “Please repeat”), meta-cognitive (e.g., “I have no idea,” “I forgot”), and blank (i.e., no response provided) responses (Zapata-Rivera et al., 2015a).

Fig. 1 A screenshot of ELLA-Math.

Lopez et al. (2021) report on a study evaluating the accuracy of the ELLA-Math prototype in correctly identifying and classifying student responses generated by middle school students. The system was found highly accurate in interpreting many of the sentences provided by students. Also, several areas for improvement were identified (e.g., handling additional types of responses and improving the robustness of the system to accommodate various types of misspellings and typographical errors). Information collected can be used to refine the internal components of the system (e.g., regular expressions and dialog scripts) following an iterative development and evaluation approach.

Zapata-Rivera et al. (2018) report on the results of a study exploring the different kinds of unexpected responses found in data collected using CBA prototypes. Unexpected responses were identified and classified into several categories by the researchers. These categories included: (a) confused (response made little sense or lacked an explanation); (b) frustrated (the student seemed annoyed by his or her interaction with the characters); (c) repetitive (the student repeated the same answers to different questions); (d) unmotivated (the student did not care to answer or provided short answers); (e) irrelevant (the student provided off topic responses); (f) asking for help (the student asked for additional information or materials); (g) gaming the system (the student tried to test the capabilities of the system); (h) attempting to communicate (the student did not answer the question and referred to previous interactions); (i) different languages (the student responded in a language other than English); and (j) giving up (the student mentioned that they want to quit). Identification of these categories may reflect students with different levels of motivation and shows the potential for the assessment system to identify these situations and react to them in a way that addresses students' frustrations and provides them the necessary supports to persist through the task. In the next section, we describe an approach for designing and implementing personalized, caring assessments that offer potential strategies for dealing with some of these situations.

CBAs and caring assessments

Personalized, "caring" assessment systems are designed to consider additional information about the student (e.g., cognitive, meta-cognitive and non-cognitive aspects) and the learning context to create assessment situations that students find engaging, and which can be used to collect valid and reliable evidence (Zapata-Rivera, 2017). Information about the learning context including socio-cultural aspects can be useful in implementing personalization approaches that positively influence student learning and can be adopted within educational ecosystems (see Fig. 2).

Different levels of "caring" (i.e., student support) can be implemented depending on the purposes of the assessment. Two common use cases include dealing with (a) student motivation issues and (b) prior knowledge or opportunity to learn. When dealing with student motivation aspects, assessments could implement student-centered approaches to deal with instances of low motivation, such as providing information to the student about why the test is administered and how the data will be used (e.g., as a learning opportunity that will help the student identify strengths and areas for improvement), incorporating motivation-oriented feedback, offering other assessment options for students to choose, and taking into account the level of motivation when interpreting the evidence collected during the assessment. Similarly, in the case where a student does not know or did not have the opportunity to learn a particular concept, the assessment could offer relevant learning materials or scaffolded activities before asking additional questions about the concept. The assessment can then take this information about the students' prior knowledge and experiences into account when interpreting the data collected (Zapata-Rivera et al., 2020).

This personalized, caring assessment approach is consistent with a broader educational emphasis on the use of Universal Design for Learning (UDL; CAST, 2018) as a framework for improving and optimizing learning for all students. UDL is a framework for the design of learning materials and environments, grounded in the idea that supporting diverse learners where they are should include careful consideration and design of learning opportunities such that they reduce barriers to access and engagement, providing learners with multiple means of (1) engagement, (2) representation, and (3) action and expression. Our framework for caring assessments introduces the possibility to incorporate supports consistent with the UDL guidelines into an adaptive assessment experience (e.g., providing multiple ways to make a response), in order to optimize the assessment experience for students, while simultaneously permitting collection of more precise evidence of students' KSAs.

Fig. 2 Personalized, "caring" assessments.

One approach to meeting students where they are and providing support are cognitive bandwidth recovery strategies (Verschelden, 2017). Cognitive bandwidth recovery strategies are designed to help students minimize the negative impacts of cognitive resources being dedicated to dealing with the effects of poverty, racism, and social marginalization, which allows students to “recover the cognitive bandwidth” required to successfully perform learning and assessment tasks. These strategies promote a growth mindset (Dweck, 2006) and self-efficacy and have potential for improving the chances of minority students to demonstrate what they know or can do. These strategies include teachers asking students who already took a particular assessment to share their experiences with other students who will take that same assessment; asking students to write about particular values or topics that decrease identity threat, increase belongingness, or promote growth mindset; co-designing assessment tasks and feedback with teachers and students taking into account aspects such as inclusion and growth mindset; taking breaks during assessments to engage students in activities that lower anxiety; providing additional time for students who start assessments late; and taking the assessment in a familiar environment where students feel safe. Such strategies could be implemented within a caring assessment framework to provide adaptive supports for a variety of social-emotional characteristics.

CBAs and student emotions

The importance of emotions during the learning process has been well documented (e.g., Baker et al., 2010; D’Mello et al., 2006; Graesser et al., 2007; Pekrun et al., 2011). In particular, research on tutorial conversations (human-human, computer-human) has documented that students experience a variety of emotions and that the experience of those emotions impact learning outcomes (e.g., Baker et al., 2010; Forbes-Riley and Litman, 2011; Graesser et al., 2007). The learning-centered emotions (anxiety, boredom, confusion, curiosity, delight, engagement/flow, frustration, happiness, surprise) were first identified during interactions with AutoTutor and were later found to be prominent in short learning sessions (30–90 min) across a variety of domains and interaction styles (D’Mello, 2013). Conversation-based learning environments in the last decade have begun detecting student emotions in real time and deploying emotion-sensitive support to students (D’Mello et al., 2011; Forbes-Riley and Litman, 2011). These emotion-sensitive interventions have shown to be particularly beneficial for students with lower prior knowledge.

Emotions during testing have received relatively less attention (see Pekrun et al., 2011, 2004, and Spangler et al., 2002, for exceptions). Early research focused primarily on test anxiety (Zeidner, 1998) and while more recent research has expanded the emotions investigated (anger, anxiety, enjoyment, hope, hopelessness, pride; Pekrun, 2006), the context has remained limited to the context of tests with traditional item formats (e.g., multiple-choice items). It is unclear how the testing context will impact the emotions experienced and how those emotions relate to test outcomes, but it is important to understand the relationship between test context and emotions to provide both support to students and accurate test outcome reporting. Thus, the creation of CBAs (and other non-traditional assessment formats) has necessitated a new round of investigations into student emotions during assessment.

A series of studies using retrospective affect judgment tasks were conducted to investigate the emotional experiences of students during CBAs (Lehman and Zapata-Rivera, 2018b). The first goal of these investigations was to identify those emotions that are most relevant to this specific testing context. Initially, a large set of emotions was explored because CBAs are a combination of conversation-based learning environments (evoking learning-centered emotions; D’Mello, 2013) and assessments (evoking achievement emotions; Pekrun et al., 2011). Ekman’s (1973) basic emotions (anger, contempt, disgust, fear, joy, sadness, surprise) were also included in this initial investigation. A consistent set of prominent emotions were found for interactions with CBAs of science inquiry and math argumentation skills: boredom, confusion, curiosity, delight, engagement, enjoyment, frustration, hope, pride. However, the findings revealed no relationship between these prominent emotions and performance on the CBAs.

A follow-up study was conducted to directly address the lack of relationship between emotion and performance (Lehman and Zapata-Rivera, 2018a). The prior studies only allowed students to report whether an emotion did or did not occur at a given point in the CBA. However, research on emotions during learning has shown that the relationship between emotions and learning outcomes may not be as simple as the presence or absence of an emotion during learning (D’Mello and Graesser, 2012; D’Mello et al., 2007). For example, research on confusion during learning has found that confusion resolution and duration impact the confusion-learning relationship (D’Mello and Graesser, 2012). In this vein, the third study allowed students to report the intensity of their experienced emotion (low, medium, high). The findings revealed that curiosity, engagement, happiness, and pride were all positively correlated with performance, but the relationship between negative emotions and performance varied based on emotion intensity (see Fig. 3). For boredom, confusion, and frustration the results showed that they were positively correlated with performance at low intensity, not correlated at medium intensity, and negatively correlated at high intensity. These opposing relationships based on emotion intensity add an interesting new twist to understanding students’ emotional experience during testing. Performance on conversations was determined by applying the Expectation-Misconception framework described above (Lehman and Zapata-Rivera, 2018a).

Fig. 3 Relationship between emotion intensity and conversation-based assessment performance.

Documenting the emotional experience is an important first step, but it is critical to determine how these findings can be applied to improve both the students' experience and the validity of test outcomes. In the case of CBAs, the structure of conversations can be evaluated through the lens of student emotions. One motivation to develop CBAs was to increase student engagement. Thus, the different paths in the conversation structure can be evaluated as to the extent that students maintain the productive state of engagement or resolve less productive states and return to an engaged state. A follow-up question, for example, that frequently elicits frustration may need to be re-designed to ensure that it provides students with the best opportunity to show what they know and can do.

Real-time, emotion-sensitive adaptations and supports are another way that information about student emotions can be leveraged to improve student experience and the validity of test outcomes. As mentioned previously, this type of support is already provided in some conversation-based learning environments (D'Mello et al., 2011; Forbes-Riley and Litman, 2011). Similar efforts targeting test-taking motivation during testing have also shown positive results in terms of both decreasing disengaged responding and increasing test reliability (Wise et al., 2006). Thus, it is not out of the question to provide this type of support in the assessment context. However, there are still potential issues with providing emotion-sensitive adaptations during assessment that must be explored. One issue is that the ability to reliably detect student emotions is not perfect, and in high stakes testing contexts, there could be serious consequences to incorrectly delivering (or not delivering) emotion-sensitive support to a student. Another important issue is fairness. Any kind of personalized, adaptive support will inherently mean that students will not have a standardized experience with the test. While this lack of standardization may have a positive impact for most students, it is vital to ensure that the differential emotion-sensitive support that students receive does not disadvantage or advantage any particular group of students.

Beyond emotions, other student-level characteristics like self-efficacy could be used to provide adaptive support to students within a caring assessment framework; in the following section, we review research examining the role of various individual differences in students' interactions with CBAs.

CBAs and individual differences

There has been long-standing interest in understanding the role of individual differences in learning and instruction (e.g., Cronbach and Snow, 1977; Jonassen and Grabowski, 1993; Snow, 1986). In general, such work has been concerned with investigating how individual-level variation in characteristics such as cognitive abilities, personality, prior knowledge, or other attributes may interact with features of the instructional tasks learners are asked to complete, resulting in different learning outcomes (Jonassen and Grabowski, 1993). Individual differences have been conceptualized in terms of both academic skills (e.g., reading or math ability) and non-academic personal qualities (Duckworth and Yeager, 2015), also referred to as non-cognitive or social-emotional competencies (e.g., persistence, self-efficacy, growth mindset, personality, etc.). Recent research has examined the utility of different approaches to assessing or measuring such individual differences via self-report surveys, situational judgment tasks, or other more direct measures

(e.g., Abrahams et al., 2019; Duckworth and Yeager, 2015; Kyllonen, 2016; Lipnevich et al., 2013; Soland et al., 2019; West et al., 2018), and has documented the individual differences that most strongly correlate with or predict academic achievement in various domains (e.g., Hattie, 2009; Kyllonen, 2012; Nofle and Robins, 2007; Richardson et al., 2012; Schneider and Preckel, 2017; West et al., 2016). Individual differences in self-efficacy and self-regulation skills appear to be particularly important, showing moderate correlations with college GPA (Richardson et al., 2012).

As with any learning or assessment experience, when students engage with CBA, they bring with them different constellations of resources and capabilities and will differ in their potential to experience barriers. For example, a meta-analysis (Schroeder et al., 2013) reported that artificial agent features such as communication modality (text-only or voice and text vs. narration-only), agent voice (no voice vs. human or computer-generated voice), appearance (non-humanoid or humanoid vs. human), animation (animated vs. static), the content domain (STEM vs. humanities), the student's grade level (K-12 vs. postsecondary), and degree of prior knowledge (moderate vs. low or high) all have a significant impact on learning from virtual agents; however, virtual agents' potential impact on assessment performance is less clear. It is thus important to understand how students' individual resources and capabilities may relate to and potentially impact their perceptions of and performance within CBA tasks.

A series of studies was conducted to investigate the role of individual differences in the context of a CBA measuring science inquiry skills (see Liu et al., 2016). The first study examined whether students' perceptions of virtual agents in the CBA (a scientist and a peer) related to CBA performance (Sparks et al., 2018). Specifically, this work evaluated whether experimental manipulations of features of the peer agent (i.e., high vs. low topic knowledge) and the type of question posed by the peer agent (i.e., asking the student to compare their observations to the peer's and choose the stronger observation, vs. asking whether the student agrees or disagrees with the peer's choice of the stronger observation) had an apparent impact on students' perceptions of both agents (measured by self-report ratings) or on task performance (measured by scores aggregated from student responses to selected response, constructed response, and conversation-based items included in the task, as described previously). Results indicated that question type had greater impact on students' perceptions than the virtual peer's topic knowledge level, such that students rated the virtual scientist as less knowledgeable and authoritative in the agree/disagree condition than in the compare condition. Agent perceptions also correlated with students' task performance, such that students who performed better on the CBA were more likely to give higher ratings to the virtual scientist, but lower ratings to the virtual peer. Students who earned "A" grades in science, or had higher performance on a standardized science assessment, were also less likely to rate the virtual peer as knowledgeable.

A second study more directly examined the individual differences that correlated with and predicted CBA performance by asking students to complete a variety of self-report measures in addition to completing the science inquiry CBA (Sparks et al., 2019). Analyses indicated that individual differences in social-emotional variables like persistence (i.e., grit; Duckworth et al., 2007), growth mindset (Dweck, 2006), cognitive flexibility (Martin and Rubin, 1995), achievement goal orientation (Elliot and Murayama, 2008), self-efficacy (Pintrich and De Groot, 1990), and self-reported interest in science (Maltese and Tai, 2010) were positively correlated with CBA performance, and test anxiety (Pintrich and De Groot, 1990) was negatively correlated. Regression analyses revealed that after controlling for demographics (urban vs. rural school, grade level) and prior achievement (standardized test scores), individual differences in cognitive flexibility, growth mindset, science self-efficacy, and test anxiety were also significant predictors of performance on the science CBA (test anxiety had a negative relationship to scores).

In a third study, those four individual difference measures found to significantly predict CBA scores were used as inputs for a hierarchical cluster analysis, which yielded four distinct profiles of students with different patterns of background variables and performance (Sparks et al., 2020). While the study found one high-performing cluster with high prior achievement, very low-test anxiety, and high levels of growth mindset, self-efficacy, and cognitive flexibility, three low-performing clusters were also observed, with potentially different contributing factors. For example, one low-performing cluster had low prior achievement as well as lower levels of growth mindset (i.e., highly fixed mindset), while another low-performing cluster had average prior achievement but relatively low cognitive flexibility, self-regulation, persistence, intrinsic value, and science interest. Pending further validation, these profiles could be leveraged to streamline the design and delivery of adaptations to CBA tasks to address and ameliorate different reasons for poor performance (e.g., encouraging a growth mindset vs. strategies to manage lack of self-regulation, perseverance, or interest), in support of the larger goals of the caring assessment framework previously described (Zapata-Rivera, 2020). Additional research is needed to understand precisely how CBAs can be effectively tailored to provide an engaging and valid experience for students within particular profiles by using information about the range of characteristics students bring to the assessment.

As illustrated above, CBAs provide fertile ground for conducting innovative research in support of designing and developing personalized learning and assessment systems, suggesting many fruitful possible future directions for further investigations.

Moving forward

Several experts were invited to provide their insights on issues regarding the use of dialog systems in assessment and learning. The following experts accepted our invitation to provide comment: Arthur C. Graesser, The University of Memphis; Sandra Katz, University of Pittsburgh; Lewis Johnson, Alelo; Andrew Olney, The University of Memphis; and Carolyn Rosé, Carnegie Mellon University.

Experts identified the main challenges for implementing assessments that make use of dialog systems. These challenges include:

- Developing authoring tools that are easy to use, linking discourse to external representations (pictures, diagrams, simulations), supporting the implementation of regular expressions that usually need to be hand-crafted, generating good hints, and designing approaches for providing feedback to conversation participants while considering assessment goals (Graesser, 2021).
- Improving natural language understanding to assess student knowledge and conceptual understanding at various levels. For example, understanding responses to deep-reasoning questions (e.g., why and how questions) and supporting student engagement with dialog-based interactions with tutoring systems (Katz, 2021). Also, assessing the forgiving tendency of dialog can be challenging (e.g., the listener usually fills in missing details). Dialog-based assessment needs to be adaptive in diagnosing student understanding (Olney, 2021).
- Validating these assessments with human judgments, which have a subjective element, and finding appropriate validation methodologies that work in the lab and translate well into educational practice (Johnson, 2021).
- Considering differences in how students treat computer agents compared to humans (Rosé and Torrey, 2005). However, computer-based dialog could be compared to using a structured problem-solving interface and thus it should be as effective in assessing knowledge and cognitive skills (Rosé, 2021).

Experts were asked to elaborate on areas for future work on CBAs. In addition to addressing the challenges mentioned above, the experts mentioned the following directions for future research:

- Exploring the use of Deep learning models known as Transformers in natural-language understanding, and investigating trade-offs typically considered in reinforcement learning to precisely measure ability while taking into account time constraints (Olney, 2021).
- Continuing to investigate the generalizability of trained models in automated assessment of conversational processes (Rosé, 2021).
- Integrating agent systems with smart phones and developing conversational guides at a meta-level (i.e., outside of the content being assessed) (Graesser, 2021).
- Measuring a variety of communicative competencies in dialog including persuasiveness and empathy. For example, communicative competences such as those relevant to the community of health workers (e.g., communicate using language at the level of the individual; communicate with individuals in a non-judgmental and appropriate manner; practice active, reflective listening and remain solution-oriented in all interactions; recognize and respond to non-verbal behavior; ask open-ended questions to solicit information from the individual; utilize affirming statements to provide positive reinforcement) (Johnson, 2021).
- Exploring the potential benefits of integrating Open Learner Modeling (OLM) technology with dialog-based tutoring systems (Katz et al., 2021). Opening the student model in a dialog-based tutoring system raises some interesting challenges such as maintaining the illusion that students are interacting with a conversational partner while exposing the system's adaptive processes, and finding approaches to share dialog-based system's evidence with students (e.g., when evidence includes lengthy explanations) (Katz, 2021).

Finally, we put together a list of resources that these experts recommended for graduate students and other researchers who are new to this area of research, in order to inspire scholars who are just being introduced to these topics to pursue related lines of work. These resources can be found in [Appendix A](#).

Building on the ideas mentioned above, we elaborate on additional challenges and future work in this area:

- As mentioned above, additional tools to support the development of CBAs that support naturalistic communication is one of the areas for future work. As more technology rich tasks are integrated into assessment and learning systems, the need for rapid development of conversations that can be used to gather evidence of constructs (e.g., using particular conversation patterns) should be considered. These authoring tools can benefit from domain, assessment and dialog systems experts as well as information collected through crowdsourcing approaches (e.g., Ramanarayanan et al., 2016).
- Continue improving NLP capabilities used in the implementation of CBAs (e.g., improving the accuracy of speech and dialog engines), developing and evaluating measurement models to score CBAs, and developing procedures for validating CBAs under different conditions (e.g., formative and summative contexts), for different subgroups of learners (e.g., English language learners, and underserved groups), and to measure additional constructs (e.g., communicative competencies).
- Additional work on implementing and evaluating cognitive bandwidth recovery strategies (Verschelden, 2017) may result in insights for improving assessment and learning systems. Additional challenges in the area of caring assessments include data privacy and security issues, the development of new communication channels and feedback loops with teachers and students, and supporting appropriate use, trust, and adoption of these assessment systems and the information they provide. Results from research in areas such as OLM and interactive score reporting can inform work on communicating assessment results and support trust in dialog systems (Zapata-Rivera, 2020).

- Future work on emotions and CBAs should focus on how to (1) utilize student emotions to evaluate and refine the design of CBAs and (2) provide on-demand support for students during the completion of CBAs. The current findings can be replicated during the development process of future CBAs to identify components of the CBA that is or is not supporting student engagement. Providing on-demand support, on the other hand, is a more complex matter as it requires both the reliable detection of emotions and the deployment of appropriate supports. The support provided to students may need to be further personalized based on student individual differences, as these characteristics are likely to impact the effectiveness of interventions. There is also the issue of fairness, as mentioned previously, so it is important to understand the impact of any support provided on the validity of test outcomes.
- With respect to individual differences in CBA, future research and development could take several different directions. One direction would be to focus on integrating CBAs within instructional programs designed to measure and develop students' social-emotional learning (SEL) competencies to further explore linkages between SEL and CBA performance (e.g., adapting CBAs based on students pre-task levels of variables like self-efficacy and growth mindset and evaluating whether those adaptations have any impact on the growth of SEL competencies when they are measured again later in the school year; developing and evaluating CBAs for learning and assessing SEL competencies, etc.). Another direction would be to expand efforts to align the structure of CBA within a caring assessment framework to the principles of the UDL framework, developing affordances of CBAs to better support the range of universal designs that could be implemented and evaluating their effects on learning and performance (e.g., as compared to the highly adaptive, dynamic context of human tutoring, or to more traditional, static assessments), thus positioning CBAs as a platform for delivering assessments that align to UDL requirements. Both strands of work would yield foundational and applied insights to support the design of adaptive, personalized assessment and learning systems.

Summary

In this article, we described foundational and applied work in the area of CBA. Through the analysis of unexpected responses found in data collected with CBA prototypes, we introduced the concept of personalized, “caring” assessments and elaborated on the implications for CBAs that consider a broader conception of the student and the context in which assessment and learning take place.

Interactive simulated environments with agents can help students learn as well as assess their learning. We clearly show the learning gains resulting from this approach to creating these types of environments for learning (see Graesser, 2016); this article extends that work to the realm of assessment with conversation-based assessment environments that elicit evidence beyond what might be possible with traditional test items.

We reviewed preliminary findings from two current areas of research on factors that may influence student performance in CBAs: student emotions and individual differences. The research on emotions has a long history of showing importance to learning and this work has been extended to the area of emotions in assessments. Specifically, emotions may affect student performance on CBAs adding construct-irrelevant variance that could obstruct measurement of content knowledge. Furthermore, emotions may dictate whether a student can display their knowledge and thus should be considered during design and personalization. The work on individual differences further highlights the need to take into account how different non-cognitive or social-emotional competencies, or other background characteristics not traditionally considered in assessment, may influence the types of evidence of students' KSAs gathered using CBAs. Thus, it is imperative that we continue to explore these variables and how they interact to affect engagement and performance in interactive simulated environments.

Furthermore, we elicited information from several experts in the area of dialog systems who elaborated on gaps in the current literature including creating authoring tools that can easily be used by teachers, integrating new deep learning models as well as exploring open-learning models, finding more sources of validation (including human ratings), discovering ways to scale up such environments by hosting them on multiple platforms, including measurement of additional competencies, and more. This feedback helps solidify the importance of taking into account a broader view of the student that includes non-cognitive factors and contextual information as part of the student model, and using this information to tune the learning and assessment experience so it is more personalized to where students are in terms of their current level of KSAs.

In sum, the goal of this article is to showcase the possibilities for assessment environments with agents that engage students in personalized conversations about target KSAs. The opportunities afforded by such environments could provide valuable feedback to stakeholders, improve measurement of target constructs, and improve students' experience with these systems. We expect this article will provide researchers with valuable information to begin (or continue) exploring the potential of using dynamic conversations within learning and assessment systems.

Resource	Description
Adamson, D., Bharadwaj, A., Singh, A., Ashe, C., Yaron, D., Rosé, C.P., 2014. Predicting Student Learning From Conversational Cues, Proceedings of Intelligent Tutoring Systems Volume 8474 of the Series Lecture Notes in Computer Science, pp. 220–229.	Describes how low-level textual features, models based on sequential discourse act labels and evidence from initial stages of collaborations can predict student success.
Chi, M., 2009. Active–constructive–interactive: a conceptual framework for differentiating learning activities. <i>Topics Cogn. Sci.</i> 1, 73–115.	Provides a framework to differentiate active, constructive, and interactive in terms of observable overt activities and underlying learning processes. This framework is used to analyze the effectiveness of interactive and constructive tasks and suggest coding schemes for activities.
Forsyth, C.M., Graesser, A.C., Millis, K., 2020. Predicting learning in a multi-component serious game. <i>Technol. Knowl. Learn.</i> 25, 251–277.	Describes a methodology for interpreting data on a fine-grained level resulting from student interaction with two or more artificial agents in a learning environment.
Graesser, A.C., Hu, X., Rus, V., Cai, Z., 2020. AutoTutor and other conversation-based learning and assessment environments. In: Rupp, A., Yan, D., Foltz, P. (Eds.), <i>Handbook of Automated Scoring: Theory Into Practice</i> . New York: CRC Press/Taylor and Francis.	Provides an overview of AutoTutor and CBAs. The significance includes the original dialogic structure of AutoTutor focused on learning and how this structure is augmented and applied for assessment in CBAs.
Graesser, A.C., 2016. Conversations with AutoTutor help students learn. <i>Int. J. Artif. Intell. Educ.</i> 26, 124–132.	Provides an overview of evidence gleaned from dozens of studies showing learning gains resulting from AutoTutor over a decade and multiple contexts.
Graesser, A.C., 2020. Learning science principles and technologies with agents that promote deep learning. In: Feldman, R.S. (Ed.), <i>Learning Science: Theory, Research, and Practice</i> , New York: McGraw-Hill, pp. 2–33.	Describes the theoretically-grounded principles that are implemented in a system for learning that helps students form a complete mental model (vs. Shallow memorization) of content with a focus on conversation-based environments.
Howley, I., Rosé, C.P., 2016. Toward careful practices for automated linguistic analysis of group learning. <i>J. Learn. Anal.</i> 3(3), pp. 239–262, http://doi.org/10.18608/jla.2016.33.12	Discusses bridging how linguistics views discourse and the actual operationalization to create frameworks of human discourse in collaborative environments based on theories from the learning sciences.
Jackson, G.T., Graesser, A.C., 2006. Applications of human tutorial dialog in AutoTutor: an intelligent tutoring system. <i>Revista Signos</i> , 39, 31–48.	Discusses the role of interactivity and the interactivity hypothesis in AutoTutor. The interactivity hypothesis suggests that any interaction aids learning above passive learning.
Johnson, W.L., 2019. Data-driven development and evaluation of Enskill English. <i>Int. J. Artif. Intell. Educ.</i> 29, 425–457, https://doi.org/10.1007/s40593-019-00182-2	Discusses a bottom-up, machine learning approach to creating dialogic systems.
Katz, S., Albacete, P., Chounta, I.A., Jordan, P., McLaren, B.M., Zapata-Rivera, D., 2021. Linking dialog with student modeling to create an adaptive tutoring system for conceptual physics. <i>Int. J. Artif. Intell. Educ.</i> 1–49.	Describes work on implementing and evaluating student modeling in a tutorial dialog system. The authors discuss future work to improve the performance of the system and to integrate tutorial dialog systems in the classroom.
McTear, M.F., Callejas, Z., Griol, D., 2016. <i>The Conversational Interface</i> , Cham: Springer, vol. 6, No. 94, p. 102.	Provides an overview of types of interfaces on various devices where humans have natural language conversations.
Naik, A., Rosé, C.P., 2020. Toward Open Domain Event Trigger Identification Using Adversarial Domain Adaptation, Proceedings of the 58th Annual Meeting of the Association for Computational Linguistics.	Explains a method for creating non-domain specific natural language conversations with a completely unsupervised approach (data enter black box models).
Naik, A., Lehman, J.F., Rosé, C.P., 2021. Adapting Event Extractors to Medical Data: Bridging the Covariate Shift. Proceedings of the 2021 Conference of the European Chapter of the Association for Computational Linguistics.	Explains an approach to analyzing conversations by comparing several different unsupervised models.
Olney, A.M., 2018. The unreasonable effectiveness of AutoTutor. In: Millis, K.K., Long, D., Magliano, J., Wiemer, K. (Eds.), <i>Deep Comprehension: Multi-disciplinary Approaches to Understanding, Enhancing, and Measuring Comprehension</i> . New York: Routledge.	Discusses the success of AutoTutor producing learning gains comparable to expert raters and resulting implications. There is a particular focus on the cost-effectiveness and relative simplicity of this system.

Introduction to classroom assessment

In the field of education there is a long tradition of using measures like tests to establish evidence of student proficiency. Measurement is the assignment of numbers to characterize a student performance event that indicates knowledge, understanding or skill. It is a quantitative approach to documenting what students know and can do. Educators also use qualitative judgments to discern student proficiency. Whether quantitative or qualitative, the process of assessment in education includes interpretation and use of the information gathered to document and/or improve student learning.

Educational assessment includes a range of different ways of gathering information, including large scale, standardized tests, locally designed quizzes and homework assignments, observations, and school district measures. In the classroom, the goal is to use assessment for improving student proficiency in relatively fine-grained learning segments or units. It is used to support teaching and learning. As such, effective classroom assessment is closely based upon and integrated with contemporary research on learning and motivation (Shepard, 2019).

Classroom assessment, then, “is a process that teachers and students use in collecting, evaluating, and using evidence of student learning for a variety of purposes, including diagnosing student strengths and weaknesses, monitoring student progress toward meeting desired levels of proficiency, assigning grades, providing feedback to students and parents, and enhancing student learning and motivation.” (Brookhart and McMillan, 2020, p. 4). In this chapter the primary emphasis is on what teachers do in gathering, evaluating, and using evidence of student proficiency.

The collection of evidence in classroom assessment occurs in the context of individual classrooms (DeLuca et al., 2019; Xu and He, 2019), and is locally controlled by the teacher, whether designed by the teacher or an external source. It is different from large-scale assessment, such as the use of standardized tests and year-end accountability tests, in both design and purpose. As pointed out by Shepard (2019), tests designed for monitoring, accountability, and selection are unable to be used effectively to improve student learning, and often undermine what is taught and student motivation. In contrast, effective classroom assessment that is based on recent sociocultural learning theories supports a culture that can enhance instruction and deep student learning. Shepard states (p. 184):

Because classroom assessment is intended to aid directly in the learning process (not merely to measure learning outcomes), it necessarily must be closely tied to instructional practices and to relevant research: on learning (in subjects such as mathematics, science, and literacy; on motivation, feedback, and self-regulation; on cognitive and sociocultural aspects of learning and identify; on curriculum; on adaptive teaching and teacher-learning; and on theories of formative assessment and grading.

Classroom assessment, as a process, includes a number of steps (see Fig. 1). Initially, fine-grained learning outcomes or targets and success criteria need to be clearly defined in terms that students can understand. This may involve deconstructing required

Fig. 1 The process of classroom assessment.

learning goals standards to clarify the nature of knowledge and skills that lead to proficiency. The purpose of the assessment is determined, as primarily formative, to enhance learning, or summative, to document current levels of proficiency. Evidence is then gathered to provide a beginning point for instruction. Embedded formative assessment (William and Leahy, 2015) is conducted concurrently with instructional activities. Following instruction and embedded formative assessment, teachers implement appropriate assessments that are primarily summative (design and selection of implemented assessments occurs both prior to and following instruction). In the final stage, use is determined, and this action needs to be based on an understanding of how grading, feedback and reporting impact student learning and motivation. This includes the use of summative assessment to improve instruction and student learning.

Two main purposes of classroom assessment: summative and formative

While classroom assessment is used for many reasons, such as serving as evidence for grading, tracking student progress, reporting to parents, improving instruction, remediation, diagnosing student misconceptions, motivating students, and teacher and school accountability, there are two core purposes – summative and formative. This section describes each of these purposes.

Summative classroom assessment

The primary purpose of summative classroom assessment is to document what students know, their skills, and other cognitive outcomes. It can be described as assessment of student performance. Summative assessments, most notably tests, papers, projects, and quizzes, are used to monitor and record student proficiency in achieving well-defined learning outcomes. Key characteristics of summative assessment include the following:

- Administered after instruction is completed.
- Focused on knowledge, comprehension, and application learning outcomes.
- Limited opportunity for students to shape, personalize or modify the assessment.
- Pre-planned, structured format.
- Used primarily for grading.
- Encourages performance-oriented student motivation.
- Whether selected-response or constructed-response items are used, tends to be objectively scored, often automatically by digital programs.
- Interpreted with reference to levels of proficiency.

Since the principle use of summative assessment is to document student learning, it has historically been tied to traditional measurement principles as applied to large-scale testing, including approaches to establish technical qualities, with an emphasis on objective scoring. This has often led to implementation of assessment principles and techniques that are not useful in promoting effective instruction and student learning. If teachers use traditional measurement concepts as a basis for classroom assessment that use selected-response items, then, classroom assessment tends to be focused more on what was learned than improving learning. As shown by recent research, in contrast, most teachers are guided in their assessment practices by a core value toward using evidence of performance to enhance student learning. This translates to a situated and differentiated perspective on classroom assessment practices, stressing the importance of individual teachers and context (DeLuca et al., 2019).

For summative assessment it is important that the nature of the assessment represents what was targeted in instruction and learning materials. The match between the content of the assessment and the learning goals and objectives is determined by a review and categorization of the items used in the assessment. In a selected-response test, in which students select an answer from provided alternatives (e.g., multiple-choice), the review of the items provides content-related evidence of validity (*validity* is the extent to which the inferences from the test, such as acceptable or unacceptable performance, are supported as reasonable). That is, with appropriate evidence of the match, it is reasonable to infer that when students perform well, they know all aspects of the learning that was planned. The match is sometimes assured by use of a table of specifications. The table is a two-dimensional chart that lists

key learning areas and types of knowledge or understanding that is emphasized. Items are then categorized according to both dimensions. The results indicate the percentage of items that measure each learning area and type of knowledge, understanding or application.

Types of summative assessment and learning targets

It is important to match the type or method of the summative assessment with the nature of the learning that is targeted. Selected-response items (e.g., multiple-choice, binary-choice, and matching) are best for assessing knowledge and simple understanding, such as recognition, recalling facts, definitions, and spelling. Selected-response items are effective when the goal is to sample a larger domain of knowledge. Constructed-response items, including essay questions, which require construction of an answer without the presence of possible answers, are well-suited to assessing more in-depth understanding, processes, relationships, and application. Performance assessments, such as making presentations, complete projects, and making products, are used to demonstrate student skills and application of knowledge in what they construct and present proficiency in the form of a report or demonstration. While performance assessments are more time consuming, they have the advantage of requiring more complex thinking to what are often authentic tasks closely related to living outside of school. The increased relevance of the tasks and resultant student engagement enhances motivation and learning but requires time to carefully develop rubrics and score answers subjectivity for grading and feedback. When used by multiple teachers, common interpretation of rubric levels is needed.

In the last two decades summative classroom assessments have been increasingly tied to year-end accountability tests. This is done to familiarize students with the format of accountability tests and assure coverage of the content on these “high-stakes” tests. Often, classroom tests include items that have been used and publicly released from previous years. However, it is clear that there are many deleterious impacts of this trend on student learning, instruction and teacher morale (Amrein and Berliner, 2003; Heritage, 2018; Shepard et al., 2018). If classroom assessments mimic high-stakes tests the items tend to focus on lower-level cognitive skills, narrow instruction and curriculum, and employ multiple-choice formats. Very recently, there is increased pressure to use items obtained from online test banks, with little systematic review of item quality or match to instruction (McMillan, 2018). School districts may also develop and employ common classroom assessments, the same test given by all teachers in the same courses and grade levels. Unless utilized for department level discussions about instruction within a unit, curriculum materials, and other instructional adjustments, these practices tend to undermine the primary purpose of classroom assessment tied to improving student learning and enhancing student motivation. Significant developments in large-scale testing have recently increased the usefulness of such assessment practices to inform teaching and learning (Brookhart and DePascale, *in press*). Large-scale testing companies have devoted extensive resources to provide assessments that can be used for assessing student growth and instruction, though there is disagreement about the utility and value of these tests as substitutes for classroom assessment.

Grading

An important function of summative assessment is to assign grades to student work. Grades are typically calculated on the basis of the percentage of selected-response items answered correctly, points given for short answer answers, or letters (e.g., A, B) for papers, presentations and projects. Percentages and points are usually converted to letter grades. Grades are also assigned to performance in relation to established standards of learning (standards-based grading).

The practice of grading is both longstanding and controversial (Guskey and Brookhart, 2019; Brookhart et al., 2016). Brookhart and Guskey (2019), in a recent review of 100 years of grading practices, found that teachers continue to use multiple factors in the determination of grades, and that even when grading tests and papers, there are often significant differences in the criteria for judging work, teacher severity or leniency, differences in tasks and item difficulty, teacher bias, differences in weighting various aspects of papers, and different grading scales. This is not surprising since teachers’ and school districts’ standards differ, especially when focused on classroom assessments. However, individual teachers also vary their grading practices. There are specific strategies that teachers can employ to support making grading more reliable, including the use of clear criteria, teacher training in assessment and grading to enhance the use of high quality test items, the use of scoring guides and rubrics to focus on dimensions of criteria and levels of performance, grading each short-answer item for all students then grading the next item, grading anonymously, and collaborating with others to review grading practices.

Feedback

Feedback from summative assessments has typically been straightforward and simple – an indication of what is answered correctly or incorrectly, total score, and grade (verification feedback). When verification is accompanied by explanations of why answers are incorrect and suggestions for further learning, students are encouraged to take further action based on that information that will enhance their learning. Time and supportive resources are needed to enable students to review and respond to feedback, especially to specify what and how they will address the feedback and revise their work. In other words, students need to act on the feedback for it to be effective. Because each student is unique, this often requires differentiated feedback to best address individual strengths and needs (Brookhart, 2017). Such differentiation is accomplished with the use of targeted, specific comments that essentially coach students to engage in further learning toward desired outcomes (Brookhart, 2020; Ruiz-Primo and Brookhart, 2018). In the end, if students do not act on the feedback, it is not effective.

The results of summative assessments for groups of students can be used to provide similar feedback to each group, and inform subsequent instruction with the group to address inadequate understanding and to modify future instruction. The teacher and/or students first identify what content and process learning outcomes from the unit need attention, what specific further steps are needed, and how eventual learning is assessed. The goal of these steps is to improve student learning once it has been documented.

Formative classroom assessment

Characteristics

The primary purpose of formative classroom assessment is to improve student learning. Since the seminal publication by Black and Wiliam (1998), formative assessment has become a major focus for classroom assessment. Heritage (2018) contends that the purpose of all classroom assessment “is to provide information that can be used to support student learning” (p. 39). Whether or not all classroom assessment can be used primarily to improve learning, as well as to document and report learning, it is clear that formative assessment, or what some have called assessment *for* learning (AfL), dominates research and writing about classroom assessment.

Formative assessment has been defined in many ways, with most a variation or extension of Black and Wiliam (2009, p. 9):

[Assessment] practice in a classroom is formative to the extent that evidence about student achievement is elicited, interpreted, and used by teachers, learning, or their peers, to make decisions about the next steps in instruction that are likely to be better, or better founded, than the decisions they would have taken in the absence of the evidence that was elicited.

This definition emphasizes that assessment *forms* instruction and learning experiences (Wiliam and Leahy, 2015). That is, the “evidence” of current student proficiency that is assessed by the teacher is used to feed back to the teacher and student to determine next steps in learning. Formative assessment is purposeful, a process of continuous gathering of evidence of student learning in relation to learning goals and then using the evidence for teacher decision making about instructional adjustments, and to give feedback to students. It is important to emphasize that formative assessment is not a specific tool or test (i.e., a formative assessment). Rather, it is a more comprehensive process that includes five essential elements that expand upon three questions – Where are students trying to go? Where are they now? How can they get there?

1. The identification of clear learning goals and criteria for evaluating student work.
2. Gathering evidence of student proficiency.
3. Evaluating gathered evidence.
4. Providing feedback to students.
5. Making instructional adjustments.

Other definitions of formative assessment include involving students and teachers collaboratively, student self-evaluation, learning progressions, a planned system that integrates metacognition and self-regulation, and domain specific and domain general differentiation across disciplines (Andrade and Cizek, 2010; Cizek et al., 2019; Brookhart and DePascale, *in press*). More expansive definitions of formative assessment have been promulgated to integrate research on instruction and learning that align with how formative assessment is implemented. In particular, as pointed out by Shepard (2019), formative assessment that is coherently linked to motivation and cognitive development is able to impact learning in an equitable manner.

Formative assessment is implemented to various extents in different ways. While teachers may only use some of the essential components, most effective formative assessment occurs when all five elements are evident. For example, a quiz may be employed to gauge student learning, but if there is ineffective feedback to the student and little or no instructional adjustment simply giving the quiz and noting results leaves out these two elements. Two main types of formative assessment have emerged – embedded and summative-based (McMillan, 2018).

Embedded formative assessment

The most powerful and effective type of formative assessment is embedded in the course of instruction. It is implemented as teaching and learning are taking place, essentially “embedded” in instruction. One type of embedded formative assessment can be described as “on-the-fly,” “at-the-moment,” or informal. It occurs spontaneously, depending how a lesson is being received, how engaged students are in learning, and how students respond to questions and prompts. This involves continuous monitoring of students while teaching, gathering evidence about how learning is developing. The evidence is then interpreted immediately to help the teacher know whether instructional correctives are needed (e.g., slowing down, giving more examples, using small groups to discuss, calling on students). Based on student responses and behavior, feedback is immediate.

Effective “at-the-moment” embedded formative assessment involves keen observation and appropriate questioning of students. Teachers need to observe both nonverbal and verbal cues to ascertain confidence, engagement, and understanding. This includes body language and facial expressions, as well as vocal loudness, pitch and rate of speaking. Questioning needs to allow sufficient wait time for student responses; questions need to be clear, succinct, and appropriately sequenced, with probing, as well as differentiated based on student ability, grade level, cultural backgrounds, and the subject matter being taught.

A second type of embedded formative assessment uses planned prompts, problems, assignments and questions that a teacher develops as an integral part of lesson planning. Less formal than a quiz or homework, use of the techniques provides the teacher with evidence of student learning to which feedback and instructional correctives can be made. Student responses are ungraded.

Formative use of summative assessment

Summative-based formative assessment, also referred to as formal formative assessment, is conducted through the use of more prescribed, structured, and scheduled sets of questions or problems that require student responses. This includes homework, quizzes, unit tests, and other tasks for which there would be a formal score to indicate student proficiency. Most of these assessments follow instruction, rather than occur during instruction. The results are gathered to inform teachers about progress of an entire class, subgroups of students, and individual students in order to contribute to a grade and inform whether any instructional course corrections are needed.

Preassessments of what students know, and their skills, are used for several purposes. While these ungraded assessments do not occur after instruction, like summative assessments, they help determine an appropriate point to begin instruction, one that matches with student knowledge to avoid either redundancy or expectations that are too high. This allows teachers to plan instruction that is at the right level of difficulty – challenging students to motivate them. Preassessments can also be used to make instruction more interesting, relevant, and engaging. Both structured exercises and quizzes are employed for assessing students' level of understanding to be able to plan instruction to build on these levels. Structured activities could include a writing assignment, group work, or targeted questioning. By combining the information obtained with other data, such as test scores, student records, and other teacher observations to provide confirmation of student understanding, student strengths and weaknesses are identified tied directly to the next instructional topic. Short, ungraded pretests of targeted learning outcomes can also identify current levels of understanding, acquaint students with what will be learned, and provide a baseline to gauge improvement in proficiency.

Homework is used to provide additional practice in applying what students are taught. It acts as a check on student learning to help determine whether students have reached proficiency. Homework performance can be used diagnostically to structure further instruction and individualized assistance. Homework is most effective when students provide unassisted answers to constructed-response questions, and when the teacher is able to provide meaningful feedback.

Summative quizzes and unit tests can be used formatively by providing teachers with an indication of student strengths and weaknesses that lead to instructional correctives, and for providing meaningful feedback to students. Beyond grades, feedback can specify areas needing remediation or further clarification or elaboration. This can enhance the impact of future instruction and improve student motivation that leads to further learning. Quizzes are effective because they are short, targeted to specific learning outcomes, and lead to immediate feedback to students about what they do and do not understand. Quiz-based, targeted feedback makes it relatively easy for students to relate their performance to how they learned the material. Unit tests, which may cover a week or more of learning, are more difficult to use formatively. This is due to the coverage of more material, the delayed nature of feedback, and the more extended gap between the result and learning process.

Classroom assessment literacy

It is generally recognized that classroom assessment is a process of inquiry and action in which teachers collect, interpret, and use fine-grained evidence of targeted student proficiency (e.g., specific outcomes related to short classroom lessons) to document and improve student learning. This process is not unlike what is used in conducting research more broadly. Questions are initiated for which data are collected, obtained evidence is interpreted, and conclusions are reached about the meaning of the results.

Defined in this way, there are three characteristics that are unique to how the assessment process is used by teachers in the classroom: 1) the emphasis on relatively fine-grained student proficiency rather than broader competencies and abilities; 2) the central role of teachers in determining and enacting the process and interpreting evidence (though both student self-assessment and peer-assessment strategies can be utilized); and 3) the dual purpose of both documenting and enhancing student learning.

These characteristics differentiate classroom assessment from a larger set of skills needed to interpret and use results from large-scale testing that focuses on larger-grained student proficiency. In both cases, testing is linked to student learning and instruction, but because the theoretical basis for how information is gathered and used is fundamentally different, the nature of teacher competencies to effectively use each type of assessment also differs. Fine-grained assessment for learning is informed most by learning theory and how teachers interact with students, while the use of larger-grained (long-cycle) assessment, from interim and year end tests, is implemented with more of a psychometric emphasis. For example, Brookhart (2011) points out that formative assessment as employed by teachers, based on information they obtain from classroom interactions with students and other fine-grained assessment, is quite different from what is advocated by testing companies in promoting the use large-scale test results for formative purposes. The dual purpose of classroom assessment also sets it apart from most large-scale testing and reflects the recognition that assessment is most productive when it can be used to improve student learning.

Efforts to identify assessment literacy

Researcher and expert efforts to suggest what teachers should know about assessment span decades, even if the term “assessment” is more contemporary than earlier language that stressed different but related concepts of measurement, testing and evaluation.

Changes from initial efforts, most of which were based on what prospective teachers need in their preparation programs, to more recent work, shows the development of recommended knowledge and skills from an application of psychometric principles to what is needed to improve as well as document learning.

The initial formal initiative to describe what teachers should know about assessment, the *Standards for Teacher Competence in Educational Assessment of Students* (1990), emphasized the application of measurement concepts for both classroom and standardized assessment. These standards have been important in framing what has been presented in textbooks, training programs, and measures to document the level of teachers' assessment competencies. Notably, Stiggins (1991), who probably first coined the term "assessment literacy," conceptualized assessment-literate individuals as having "a basic understanding of the meaning of high- and low-quality assessment and are able to apply that knowledge to various measures of student achievement" (p. 535).

Two significant efforts, involving multiple professional groups, have promulgated classroom assessment standards. *The Student Evaluation Standards: How to Improve Evaluations of Students* (Joint Committee on Standards for Educational Evaluation, 2003) was the first set of competencies dedicated to assessment use at the classroom level, with minimum attention to standardized testing. The 2003 *Standards* represents a massive, systematic effort to identify classroom assessment competencies and demonstrates movement toward practices that focus on improving student learning. Interestingly, though, there is little explicit language that relates assessment to instruction (the term formative assessment is not used). The emphasis is on the gathering of summative evidence that results in accurate and fair reporting of student proficiency. The overall message is action-oriented – what do teachers, administrators, and policy makers need to understand to enhance teachers' "ability to design and implement the most useful, proper, feasible, and accurate classroom evaluation practices?" (p. 13).

The Classroom Assessment Standards for PreK-12 Teachers (Joint Committee on Standards for Educational Evaluation, 2015) is a revision of the 2003 *Standards*. The 2015 *Standards* shows further evolution toward the central role of student learning in assessment, reflecting an effort to move both the organization and nature of the competencies toward having a positive impact on student learning. Over several years, sources of input, including a substantial review of literature, feedback of drafts from groups of practitioners, researchers, members of the Joint Committee, field trials, national hearings, and a validation panel, were used to establish and verify the standards. The 2015 *Standards* are organized into three domains: Foundations, Use, and Quality. The Foundations domain contains six standards that address essential assessment principles that will enhance instruction and student learning (purpose, learning expectations. For example, the first standard in the Foundations domain, Purpose, states clearly that results from assessment should be used to improve learning. The second standard, Learning Expectations, points to the importance of appropriate alignment between assessment and learning opportunities. The third, Assessment Design stresses student opportunity to show learning, and the fourth standard addresses student engagement in assessment that will improve learning. The second domain, Use, moves from purpose and design to showing how results should be used to support learning, including standards on how student performance is analyzed, effective feedback, instructional follow up, and grading. The Quality domain contains standards such as the importance of cultural and linguistic diversity, exceptionality, fairness, reliability, and validity. Overall, 8 of 11 standards in the first two domains directly reference student learning and/or instruction.

While the emphasis in the 2003 *Standards* was on describing teacher knowledge and skills, the 2015 *Standards* extend this focus to using assessment evidence to inform and improve instruction and student learning. The newer standards are much more concise and user friendly, with a comprehensive emphasis throughout on how implementation of the right kind of quality assessment practices will improve instruction and student learning.

The move toward greater emphasis on the impact of assessment on students is demonstrated in several research efforts to identify essential teacher assessment competencies. DeLuca et al., (2016) examined 15 documents from six countries published since 1990 that explicitly addressed standards or competencies for literacy related to student assessment. Their analysis showed a swing in conceptualizations of teacher assessment competencies to focus less on summative and standardized tests, and more on fairness, assessment for learning, communication of assessment results, and support for teachers. In another comprehensive review, Xu and Brown (2016) identified 100 peer-reviewed publications from 1985 to 2015 that focused on teachers' assessment literacy, competence, and professional development. The purpose was to synthesize findings from empirical studies and expert recommendations to suggest a framework that integrates knowledge and skills with measures of assessment literacy and needs for pre- and in-service education. The three major themes presented (knowledge and skills within assessment literacy, assessment education and its relationship with various mediating factors, and contextual considerations of assessment literacy) and ten subthemes are used to suggest a conceptual framework in which knowledge about assessment is integrated with classroom contextual factors, individual proclivities and values of teachers, and socio-cultural and institutional factors.

Pastore and Andrade (2019), employing a Delphi inquiry with 35 international experts on educational assessment and teacher education, propose a model of teacher assessment literacy organized by three components: (1) a conceptual knowledge dimension (what, why and how to assess, data analysis, and effective reporting); (2) a praxeological dimension (assessment in practice, navigating multiple assessment demands and use of assessment data); and (3) a socio-emotional dimension (sense-making of assessment practices, fairness, and awareness of power dynamics).

Components of classroom assessment literacy

Components (i.e., competencies) of classroom assessment literacy build upon and update existing lists of assessment standards using theories of learning and motivation, research on formative assessment, and the growing importance of student perceptions

about assessment as a critical link between what is shared with students about their performance and subsequent impacts on learning and motivation. The components are based on the following:

1. Practicality is critical to use. Teachers will best understand and implement classroom assessment practices that are meaningfully related to the process of assessment and instruction. Hence, suggested competencies are organized by how teachers plan, implement and use assessment.
2. Classroom assessment for students is a sociocultural and emotional, as well as cognitive, experience (Brown and Harris, 2016). As a process that involves interactions between students and teachers, it is fundamentally relational in which teacher values and perspectives are integrated with students' cultural backgrounds (Looney et al. (2017)). As a result, teacher-student relationships shape how students react to and gain meaningfulness from assessment results.
3. Classroom assessment is best conceptualized as a set of practices that are implemented *with* and *for* students, not something done *to* students. These suggested competencies emphasize how assessment practices are implemented to have positive impacts on not only standards-based knowledge and skills, but other important outcomes, such as emotions, motivation, attributions, self-regulation and self-efficacy.
4. To be effective, classroom assessment competencies must be framed within what we know about how students learn and how they are motivated. In particular, recent constructivist and sociocultural models of learning need to be employed to provide meaningful connections between assessment and instruction. Implementing these models promotes the use of challenging, authentic assessment tasks that increase intrinsic motivation and feelings of competence.
5. Like instruction, the process of classroom assessment is contextually bound and influenced. Application of assessment methods, interpretation, and use is influenced by the nature of students in a particular class (e.g., skill level, responses to different types of assessments and feedback), subject matter, level of schooling, teaching style, teacher beliefs about what is important to emphasize, the relative influence of high-stakes tests, and other contextual factors. As related to a process of inquiry, then, these factors need to be understood and considered in decision-making, especially with respect to grading. This suggests that while it is helpful to articulate a single set of competencies, the reality is that the process of inquiry and action is individualized to particular settings.

The classroom assessment components presented here are organized into four categories. The first and second categories, Foundational Concepts and Foundational Influences, list areas of knowledge and understanding that are needed for planning and using classroom assessment. The third category, Action, shows skills needed for how assessment is designed, implemented, scored. Finally, based on foundational knowledge and evidence gathered, teachers need to consider the consequences of classroom assessment – how the process influences students cognitively, emotionally, and behaviorally beyond the immediate assessment task and receipt of scores.

Foundational concepts

- *Classroom Assessment as a Process of Inquiry.* Teachers need a thorough understanding of the nature of classroom assessment as a sequenced progression of steps that involve inquiry and action, and how this process is different from “testing” and large-scale assessment. There is a need to pay particular attention to the role of professional judgment in all phases of the process (Looney et al., 2017).
- *Purpose.* Teachers need to understand the formative and summative purpose(s) of a particular classroom assessment event. Formative assessment focuses on improving student learning; summative on documenting proficiency. A complete consideration of purpose should encompass the extent to which other reasons for assessment are important, such as whether they need to help prepare students for standardized testing, sort students for selection, use for providing feedback, identify misconceptions or learning errors, to craft next instructional steps that will support students in their learning, to support students' engagement in assessment of their own work (self-assessment), and develop dispositions and traits. Being clear about all aspects of purpose will enable teachers to select the most appropriate types of assessment to impact students as aligned with learning goals, standards and targets, and will provide a comprehensive set of considerations in designing and implementing assessment.
- *Types of Assessment Items and Tasks.* Like purpose, knowledge about different types of assessment items (e.g., selected-response, constructed-response, oral questioning) and tasks (e.g., performance-based, portfolio, student self-assessment, peer-assessment), is fundamental to good assessment. Teachers need an understanding of the strengths and limitations of each (which types are best for gathering evidence on different learning targets), how students are affected by different types of assessment (e.g., in test preparation), and what is needed to prepare students for the assessment.
- *Quality.* Validity, reliability, and fairness form the foundation of high-quality assessment. In particular, teachers need a thorough understanding of sources of error that contribute to the results obtained from summative assessment, especially factors intrinsic to the student, bias in scoring, and limitations from sampling content to be tested. Evidence of validity and reliability of classroom assessment (whether qualitative insights into student understanding or scores on an assessment) is more a matter of alignment between learning goals and elicited evidence and repeated convergent evidence and collaborative evaluation and judgment than calculating correlations among different measures.
- *Content and Pedagogical Knowledge.* A key element of effective classroom assessment is being able to apply appropriate models of learning in a field (Pellegrino et al., 2001; Shepard, 2006). This requires in depth content and pedagogical knowledge in the domain to enable teachers to deconstruct standards, know what is most important to assess, help students understand learning

targets, and anticipate and plan for student misconceptions (Schoenfeld, 2017). This leads to improved alignment between what is most important for students to learn with assessment, and enables teachers to provide clear explanations of targets and criteria.

Foundational influences

- *Assessment Environment.* Similar to other aspects of classroom climate or environment, teachers establish norms and expectations for summative and formative classroom assessment. The resulting classroom assessment environment influences how students prepare for, take, and respond to assessment. A positive environment, one that values the formative purpose of assessment, uses authentic, meaningful and relevant tasks, engages students in self-assessment, promotes the use of feedback, and values an expectation to learn from being wrong, will enhance learning and motivation.
- *Student Perceptions.* Student perceptions of assessment include their beliefs and feelings about the assessment experience. These perceptions, occurring prior to, during, and after a summative or formative assessment event, are key elements in determining the meaning of the performance and teacher feedback, as well as subsequent student behavior. While a relatively new topic of research in the assessment field, extensive work in other fields has established the central role of perceptions in mediating meaningfulness and behavior. For example, students who exert little effort in preparing for an assessment (perhaps because they know it will not be challenging), may respond indifferently to good performance compared to students who exert much effort; novel forms of assessment are perceived as more interesting and engaging; and emotional responses to assessment-based achievement can vary from hope, pride, and contentment, to anxiety, anger, and hopelessness, each of which impacts the receptivity of feedback, attributions, and further behavior (Vogel and Pekrun, 2016). Student perceptions also play a significant role in sociocultural dynamics within the classroom assessment environment.
- *Student Engagement.* Student involvement in assessment is an essential aspect of high-quality classroom assessment. Research shows how engagement in formative assessment is related to the development of self-regulation and self-determinism, and engagement in summative classroom assessment is related to goal orientation and self-efficacy (Andrade and Heritage, 2018). Student engagement and involvement is important so that assessment is a shared experience, rather than something that is done to them. Students can be included in many aspects of assessment that enhance their understanding of what needs to be learned (targets), how criteria are used to evaluate performance (e.g., using criteria to distinguish between surface and deep understanding), and how feedback can be used to move from current to targeted levels of proficiency. Engagement is enhanced with both self-assessment and peer-assessment. Each involves the student in thinking that promotes better understanding of current levels of proficiency, what further learning is needed, and how feedback from formative assessment can be used in self-regulation.

Action

- *Designing and Selecting Appropriate Assessments.* Teachers need to know the strengths and limitations of different types of summative and formative assessments (e.g., oral, traditional tests, performance-based, portfolio, student self-reports of dispositions, student self-assessment), as well as principles for designing high quality items and tasks and formatting (e.g., spacing, use of diagrams, computer-based formats). Overall, students respond positively to appropriate, high quality assessment, and tend to discount poorly constructed items or what they perceive as hastily constructed tasks. Furthermore, when students believe an assessment is fair and challenging, preparation effort is greater and more appropriate attributions are formed from performance. It is not simply a matter of applying rules for what makes items good – it is just as important to be aware of item difficulty and student perceptions of different types of assessments.
- *Administration.* A widely recognized, key element to successful summative assessment is knowing how to appropriately administer the test, assignment or task. Setting the right climate, knowing how to prepare students, determining time frame, responding to questions, preparing directions, and other administrative details are important. Students also need to understand the importance of responding honestly to informal questions about their understanding and to self-assessments for effective formative assessment. Honesty is in part developed as students see that teachers respond constructively to those admissions and try alternative strategies to support student learning.
- *Scoring.* Virtually all standards document and lists of competencies recognize the need for knowing how to score student performance. While scoring selected-response items is straightforward, the use of criteria and rubrics for constructed-response short answer and essay items, performance assessments and portfolios requires skill in developing clearly worded rubrics that show how specific criteria develop across increasing levels of sophistication and selecting exemplars of work to illustrate each level. For summative assessment, teachers need to know how to calculate composite scores. For formative assessment scores are accompanied by teacher feedback that identifies areas for improvement.

Consequences

- *Instruction.* Assessment informs instruction in a number of ways. Teacher questioning as part of formative assessment, based on an interpretation of student performance, can include use of a specific sequence of questions, questions that scaffold learning progressions, and appropriately challenging questions that can be directed to individual students or to groups. What do students understand and/or misunderstand? What new materials or approaches to learning should students engage in? Are further

examples needed? As a result of summative assessments, is there a need for individual tutoring, review of content, or different assignments? From evidence provided, what further instruction is needed to deepen understanding? Is additional modeling of a skill needed? What common misconceptions were revealed? What are implications for instruction for future groups of students? Teachers need to know how to make conscious, well-planned connections between assessment data and subsequent teaching and learning experiences that move students toward greater proficiency.

- *Feedback.* Appropriate feedback can have powerful positive impacts on student performance, particularly from formative assessment, as well as on motivation (Ruiz-Primo and Brookhart, 2018). Characteristics of effective feedback are well documented; integrating this knowledge as part of classroom assessment literacy has great potential to benefit students. Beyond knowing how to provide effective feedback, it is also essential for teachers to understand how students respond to teachers' responses to their work (William and Leahy, 2015).
- *Learning.* The consequences of assessment on learning comprise a key focus of recent efforts to define classroom assessment literacy. This includes how assessment practices influence student learning throughout the assessment process. Learning is affected by how students prepare for different types of assessments (e.g., selected-response compared to constructed-response) on different types of learning targets (deep understanding or surface knowledge), level of difficulty, and the amount learned. Learning is impacted as students do the assessment, as well as what they learn from their results and feedback. Learning is not restricted to curriculum-based targets. There is good evidence that through the process of assessment students can learn important self-regulation skills (Andrade and Heritage, 2018), positive self-efficacy, responsibility, and persistence in face of difficulties and barriers (McMillan, 2018).
- *Motivation.* While there has been much emphasis on assessment for learning, it is also important to understand how assessment impacts student motivation in the classroom (e.g., preparing for and taking tests), as well as how the development of motivational traits is influenced by the assessment experience. Extensive research in achievement motivation, self-regulation, attributions and goal orientation, for example, show how assessment performance is related to the development of self-efficacy, intrinsic motivation, responsibility, internal attributions, and risk-taking. Recent research in the relationship between self-regulation and assessment is especially persuasive (Andrade and Brookhart, 2016; Andrade and Heritage, 2018). Through self-assessment and opportunities to plan their learning based on proficiency in relation to learning targets, monitor progress, and evaluate their performance (especially when unsuccessful), students enhance their self-regulation skills.
- *Grading and Reporting.* Summative classroom assessment is used for grading and reporting. Given the long-standing variations in teachers' use of different factors in how they grade (Brookhart et al., 2016) teachers need a full understanding of how grading is done fairly and accurately, and how it affects students. For example, including a score of zero has an overly negative impact on grades due to unequal scale intervals, and averages can mask improvement and give undue influence to isolated, extreme scores.

These components have been selected to help educators frame what is most important about what teachers need to know and do when implementing classroom assessment. Compared to what would be appropriate for assessment literacy or data literacy more broadly, the conceptualization does not include the need to know about, interpret and use standardized tests. The contention is that classroom assessment has emerged as much more than assessment in the classroom, or the application of measurement principles to student assessment. Classroom assessment is now conceptualized as a thoughtful and complex process, focused as much on improving student performance as documenting it.

Glossary

Alpha The probability of a Type I error (rejection of a true null hypothesis)

Analysis of variance (ANOVA) A statistical test used to compare the means of three or more populations

Factor An Independent (treatment) variable

F ratio $S^2_{\text{bet}}/S^2_{\text{W}}$; between-groups variance estimate divided by the within-groups variance estimate

Grand mean The mean of all scores in all the treatment conditions

Interaction effect In analysis of variance, the joint effect of two or more independent variables that cannot be predicted from the main effects

Level(s) Different values of an Independent variable (factor)

Main effect In analysis of variance, the mean differences among the levels of one factor averaged across the levels of the other factor

Multivariate analysis of variance (MANOVA) A multivariate version of analysis of variance used to compare means among groups on multiple dependent variables

Omega-squared ω^2_{bet} ; a measure of effect size for analysis of variance

Orthogonal comparisons Comparisons that are unique and do not overlap

Planned comparisons Statistical tests used in place of ANOVA when the researcher knows in advance which comparisons are of interest

Post hoc comparisons Statistical tests performed after obtaining a significant value of F that indicates which means are significantly different

Power The probability of rejecting a false null hypothesis

Sum of squares (SS) Sum of the squared deviations from the mean

Type I error Rejection of a true null hypothesis

Introduction

Imagine that you are superintendent of a school district and you wish to compare the mathematics competency of students enrolled in seven high schools. You randomly select 30 seniors from each school and give them a mathematics achievement test. Your null hypothesis is that the mean mathematics achievement scores in the seven populations (the seven high schools) are equal, that is, there is no difference in scores among the schools. How should you analyze the results? If you had decided to test for differences between all pairs of means with use of a t -test, you would have to conduct 21 tests. Suppose that you had decided in advance to set the probability of a Type I error (rejection of a true null hypothesis) at 0.05. This means that when testing for a difference between two population means, in 20 replications of the same study (drawing independent random samples of the same size each time) you would expect the results of one of the t tests to be statistically significant even if there is no difference between the population means. Although for any one test, alpha (probability of a Type I error) is 0.05, with 21 independent tests, the probability of making at least one Type I error is $p = 1 - (0.95)^{21} = 1 - 0.34 = 0.66$. Thus, if you found a statistically significant difference for one or two of your 21 tests, there is a high probability that the result(s) was due to a Type I error rather than to a true difference between groups.

You need a test that allows you to make multiple comparisons among means while holding alpha steady at a preselected level. To this end, Ronald Fisher (1890–1962) developed analysis of variance (ANOVA) in the 1920s. An interesting feature of ANOVA is that although it is a test for differences among population means, it can be conducted without calculating the value of any of the sample means. It may seem odd that we are interested in testing for differences in population means and yet we use a statistical procedure referred to as analysis of “variance.” We will learn below that the test simply involves the ratio of two variances.

The logic of ANOVA

ANOVA involves a categorical independent variable, often referred to as a factor or treatment, and a continuous dependent variable (or outcome). When testing for differences among population means on the dependent variable across the levels of the independent variable, variation in scores can be due to two things: chance and treatment effect. Here, a treatment effect refers to true differences among population means. When there is no treatment effect, all population means are the same. As the scores in any one sample are drawn randomly from the same population, the scores can differ from one another, and from the sample mean, only due to chance. However, scores in different samples, as well as sample means, can differ from one another due to chance, but also because the experimental treatment has an effect. If there is no treatment effect, scores in different groups will differ only because of chance. Thus, when the null hypothesis (there is no treatment effect) is true, the variation of scores around the sample means within each sample ($X - \bar{X}$) and the variation of sample means from the grand mean ($\bar{X} - \bar{\bar{X}}$; the grand mean, $\bar{\bar{X}}$, is the mean of all scores) will both be a reflection of variation in scores due to chance factors.

For any study of two or more samples, the amount by which a score differs from the grand mean ($X - \bar{\bar{X}}$) can be partitioned into two parts: the amount by which the score differs from its own sample mean ($X - \bar{X}$) and the amount by which the sample mean differs from the grand mean ($\bar{X} - \bar{\bar{X}}$). The partition of $X - \bar{\bar{X}}$ is represented by the following equation:

$$X - \bar{\bar{X}} = (X - \bar{X}) + (\bar{X} - \bar{\bar{X}}) \quad (1)$$

As the name suggests, in ANOVA, we are going to work with variance estimates. Variance estimates are calculated by dividing the sum of the squared deviations from the mean (often called sum of squares, and abbreviated SS) by the degrees of freedom (df). We can calculate the sum of squares total (SS_{total}) for two or more samples by calculating the deviation from the grand mean for every score, squaring each deviation score, and then summing (Σ) all the squared deviations from the grand mean:

$$SS_{\text{total}} = \sum^{\text{all}} (X - \bar{\bar{X}})^2$$

Look again at Eq. (1). You can see that we could also calculate SS_{total} by squaring $(X - \bar{X}) + (\bar{X} - \bar{\bar{X}})$:

$$\sum^{\text{all}} (X - \bar{\bar{X}})^2 = \sum^{\text{all}} (X - \bar{X})^2 + \sum^k n (\bar{X} - \bar{\bar{X}})^2$$

where:

n = the number of scores in a particular group

k = the number of samples

When we square $(a + b)$ there is a middle term, here $2(\bar{X} - \bar{\bar{X}}) \sum (X - \bar{X})$, but in this case, it is always zero. What has been accomplished is the partitioning of the total sum of squares into two parts: (1) $\sum^{\text{all}} (X - \bar{X})^2$, called SS_{within} (or SS_{error}), a reflection only of chance factors when drawing samples, and (2) $\sum^k n (\bar{X} - \bar{\bar{X}})^2$, called SS_{between} , a reflection of both chance factors and treatment effect (when the population means are different). Thus,

$$SS_{\text{total}} = SS_{\text{within}} + SS_{\text{between}}$$

We can now divide the separate sums of squares by their respective degrees of freedom to obtain variance estimates. The degrees of freedom for SS_{total} is the total number of scores minus one: $n_{\text{total}} - 1$. For SS_{within} (abbreviated SS_{w}), the degrees of freedom is calculated by adding $n - 1$ for each sample: $n_{\text{total}} - k$. For SS_{between} (abbreviated SS_{bet}), degrees of freedom is the number of samples minus one: $k - 1$.

The end result is two variance estimates. One is the within-groups variance estimate, $s_{\text{w}}^2 (= SS_{\text{w}} / df_{\text{w}})$, which is an estimate of the variance due to chance. It is sometimes called mean square within or mean square error. The other is the between-groups variance estimate, $s_{\text{bet}}^2 (= SS_{\text{bet}} / df_{\text{bet}})$, which is an estimate of the variance due to chance plus any treatment effect. It is sometimes called mean square between. When there is no treatment effect, both are estimates of the same thing. Thus, when the null hypothesis

is true (i.e., there is no treatment effect), the ratio s_{bet}^2/s_w^2 , called the F ratio, should be about 1.0. As noted above, because s_{bet}^2 is an estimate of the variance due to chance plus any treatment effect, when the null hypothesis is false (i.e., there is a treatment effect), s_{bet}^2 will exceed s_w^2 , and the greater the treatment effect, the more is the amount by which s_{bet}^2 will exceed s_w^2 . Due to sampling variation, we expect the value of the F ratio to be different with every replication of a study (employing new randomly drawn samples of the same size). However, if we set $\alpha = 0.05$ and obtain a value of F that would have occurred by chance less than 5% of the time (if the null hypothesis were true), we reject the null hypothesis and conclude that there is a treatment effect (i.e., the treatment effect reliably exceeds effects due to random chance). Finding the critical value for F will be discussed in the example below.

Computation of F : an example

Let us look at an example. Suppose that we wish to compare two new methods for teaching mathematics with the standard method. We randomly draw a sample of ten students for each method and use each method for 1 year, at the end of which we administer a mathematics achievement test to each student. The hypothetical results are as follows:

Standard method (X_1)	Method 2 (X_2)	Method 3 (X_3)
68	85	62
70	90	76
75	80	74
65	78	70
55	82	58
80	86	78
72	92	74
78	76	80
60	94	65
74	84	75
$\sum X_1 = 697$	$\sum X_2 = 847$	$\sum X_3 = 712$
$\bar{X}_1 = 69.7$	$\bar{X}_2 = 84.7$	$\bar{X}_3 = 71.2$

$$\bar{\bar{X}} = 2256 / 30 = 75.2$$

We now calculate SS_{total} , SS_w , and SS_{bet} :

$$\begin{aligned} SS_{\text{total}} &= (68 - 75.2)^2 + (70 - 75.2)^2 + \dots (65 - 75.2)^2 \dots \\ &\quad + (75 - 75.2)^2 = 2722.8 \\ SS_w &= (68 - 69.7)^2 + (85 - 84.7)^2 + (62 - 71.2)^2 \dots \\ &\quad + (70 - 69.7)^2 + (90 - 84.7)^2 + (76 - 71.2)^2 \\ &\quad \cdot \quad \cdot \quad \cdot \\ &\quad \cdot \quad \cdot \quad \cdot \\ &\quad \cdot \quad \cdot \quad \cdot \\ &\quad + (74 - 69.7)^2 + (84 - 84.7)^2 + (75 - 71.2)^2 = 1357.8 \end{aligned}$$

$$SS_{\text{bet}} = 10(69.7 - 75.2)^2 + 10(84.7 - 75.2)^2 + 10(71.2 - 75.2)^2 = 1365$$

There are formulas to calculate SS_{total} , SS_w , and SS_{bet} that are easier to use for hand calculations than using deviations from means, but they do not provide you with a basic understanding of ANOVA (see King et al., 2018). (It is these formulas that allow you to compute F without ever having calculated a single mean.) It is customary to place the results in a summary table, often called an ANOVA table:

Source	SS	df	s^2	F
Between groups	1365	2	682.5	13.571
Within groups	1357.8	27	50.29	
Total	2722.8	29		

Be sure to place between groups first, above within groups, to set up the proper ratio. As a check on your work, SS_{bet} plus SS_w should equal SS_{total} , and df_{bet} plus df_w should equal df_{total} (s_{bet}^2 plus s_w^2 does not equal s_{total}^2). Note that textbooks also refer to the variance estimates (s^2) as mean squares (MS) because they represent a type of average of a set of squared numbers.

The calculated F ratio is a random variable that follows a particular probability distribution known as the F distribution. In order to determine if our obtained value of F is statistically significant, we must use a table for the F distribution, found in any introductory statistics textbook. The table provides critical values of F . When our obtained value of F is equal to or greater than the critical value, it indicates that our result is statistically significant (i.e., has a low probability of occurring by chance, assuming the null hypothesis is true). The F distribution varies as a function of two parameters: df_{bet} and df_{w} . Critical values of F are found at the intersection of df for the numerator (2 in our example) and df for the denominator (27 in our example), and in this case, the critical values are 3.35 for $\alpha = 0.05$ and 5.49 for $\alpha = 0.01$. Thus, in our example, the probability of a Type I error was less than 0.01, that is, the result is statistically significant. In addition to your F statistic and p -value, you should also provide a measure of effect size when reporting results. One commonly used measure for independent-groups ANOVA is omega-squared (ω_{bet}^2) (see King et al., 2018). It gives us a population-based, rather than a sample-based, estimate of how much of the proportion of the variance in the dependent variable (in this case, mathematics achievement) was attributed to the different levels of treatment (in this case, teaching method). The formula for estimating omega-squared ($\hat{\omega}_{\text{bet}}^2$) can be written as:

$$\hat{\omega}_{\text{bet}}^2 = \frac{SS_{\text{bet}} + (k - 1)s_{\text{w}}^2}{SS_{\text{total}} + s_{\text{w}}^2}$$

where, in our example, $k = 3$. The other quantities can be obtained from the ANOVA table. Here, $\hat{\omega}_{\text{bet}}^2 = 0.53$.

Interpreting a significant F value

Independent-groups ANOVA can be used with two samples, in which case F is the square of the t -statistic that compares the two sample means. A statistically significant result indicates that one population mean is either less than or greater than the other. What does it mean when we obtain a statistically significant value of F for three or more samples? In this case, it tells us only that there is a difference among the population means. It does not tell us the manner in which they differ. For three groups, all three population means could be different from one another, or one could be greater than the other two, etc. To determine which means are significantly different from others, we normally use *post hoc* (*a posteriori*) comparisons. Some of the most commonly used tests are Duncan's multiple-range test, the Newman-Keuls test, Tukey's Honestly Significant Difference (HSD) test, and the Scheffé test. Duncan's test is the least conservative with regard to Type I error and the Scheffé test is the most conservative. An explanation of these tests is beyond the scope of this article, but most textbooks will provide a full explanation of one or more of them. However, before you can use any of them you must first have obtained a significant value of F . In our example, all four *post hoc* tests would reveal that teaching method 2 is superior to the other two methods, which did not significantly differ from one another.

Although the variance decomposition described above always remains true in ANOVA, some underlying assumptions are required when testing hypotheses. The first is that the populations from which the samples are drawn are normally distributed. Moderate departure from the normal bell-shaped curve does not greatly affect the outcome, especially with large-sized samples (Glass et al., 1972). However, results are much less accurate when populations of scores are very skewed or multimodal (Tomarken and Serlin, 1986), which is frequently the case in the behavioral sciences (Micceri, 1989). In this case, you should consider using the Kruskal-Wallis test, an assumption-free (nonparametric) test for the independent-groups design (see King et al., 2018). This is especially true when using small samples. A second assumption is that of homogeneity of variance; that is, the variances in the populations from which samples are drawn are the same (Rosopa et al., 2013). A variety of statistical tests exist to determine whether this assumption is violated (Rosopa et al., 2013, 2016). This can be a major problem when variances differ considerably across samples and is less of a problem if you use samples that are of the same size (Milligan et al., 1987; Tomarken and Serlin, 1986). Fortunately, existing research has found that alternative procedures (e.g., weighted least squares regression and the use of heteroscedasticity-consistent covariance matrices) are relatively unaffected by the violated assumption regardless of differences in sample sizes and are readily available in modern statistical software (Rosopa et al., 2018, 2013).

Although ANOVA is useful when studying a single dependent variable (e.g., mathematics achievement), it can be extended to designs where data is collected on more than one dependent variable. For example, an educational researcher may be interested in the effects of three modes of teaching (face-to-face, online, or hybrid) on three dependent variables—mathematics achievement, reading comprehension, and school self-efficacy. With students randomly assigned to treatments and measured on the three dependent variables at the end of the school year, the researcher could analyze the data using a multivariate version of ANOVA known as multivariate analysis of variance (MANOVA) (Rencher and Christensen, 2012). While ANOVA relies on the F ratio to compare the population means of three or more groups, in MANOVA, there are four statistical tests available to compare population means on multiple dependent variables across three or more groups. Rencher and Christensen (2012) describe the general situations in which one multivariate test tends to outperform the others.

The repeated-measures design

ANOVA can also be used with the repeated-measures design. For example, assume that 20 students had achievement scores under three conditions (pretest, posttest, 6-month follow-up). This simple design is also referred to as a one-way within-subjects design.

The major difference from the independent-groups design is that SS_w is partitioned into two parts: (1) SS_{subjects} , which is a reflection of the variability in scores resulting from individual differences, and (2) $SS_{\text{residuals}}$, a reflection of the variability in scores due to chance. Although three variance estimates can be calculated (s^2_{subjects} , s^2_{bet} , and s^2_{resid}), normally we are interested only in the F ratio $s^2_{\text{bet}}/s^2_{\text{resid}}$ to determine if there is a statistically significant difference among groups. (We are usually not interested in whether or not individuals differ.)

An additional assumption with this design, when there are more than three conditions, is sphericity (King et al., 2018). It requires that the population variances of the differences between the levels of the within-subjects factor are the same. When there are only two conditions, there is only one set of differences, and therefore, only one variance. Thus, the assumption cannot be violated.

When you have three or more conditions and the sphericity assumption is violated, one alternative data-analytic approach is the use of an F ratio with an adjusted- df that accounts for violating the assumption. Of the adjusted- df approaches that are available for the univariate F ratio, the method by Greenhouse-Geisser strikes a good balance between controlling Type I error and having adequate statistical power. In other words, when the null hypothesis is actually false, it has a high likelihood of detecting a treatment effect compared to other approaches (Maxwell et al., 2018). Another alternative is the use of MANOVA which does not require the sphericity assumption. The MANOVA approach for analyzing repeated measures data actually focuses on the differences between the levels of the within-subjects factor. For example, with three levels, the difference between level 1 vs. level 2 and level 2 vs. level 3 is analyzed in MANOVA. Although the MANOVA approach for analyzing data from a repeated measures design does not require the sphericity assumption, if the assumption is not violated, the usual F ratio tends to have greater statistical power than MANOVA (Maxwell et al., 2018).

Two-way ANOVA

In the previous example, we examined the effects of three different teaching methods on mathematics achievement scores using an independent-groups design. There was only one treatment variable—teaching method. However, ANOVA allows us to study two or more treatment variables (called factors) simultaneously. Suppose, for example, that we were also interested in whether the amount of time devoted to teaching mathematics affected achievement scores. Rather than conducting two separate studies, we can study both factors (teaching method and time spent teaching) simultaneously using a two-factor ANOVA design. If we study all three teaching methods (referred to as levels of the factor teaching method) and two different durations of time spent teaching (two levels; e.g., 45 min per day vs. 90 min per day), we have a 3×2 design. Let us suppose that we select eight students randomly for each of the six independent conditions (standard teaching method for 45 min per day, standard teaching method for 90 min per day, etc.) and after 1 year we obtain the following mathematics achievement scores:

		Teaching method			
Teaching time	Standard method	Method 2	Method 3		
45 min	60	73	62		
	80	87	74		
	68	76	63		
	72	84	73		
	64	83	64		
	76	77	72		
	69	81	67		
	71	79	69		
	$\bar{X} = 70$	$\bar{X} = 80$	$\bar{X} = 68$		
90 min	65	92	63		
	81	106	77		
	68	103	70		
	78	95	68		
	70	97	70		
	76	101	72		
	72	99	67		
	74	99	73		
	$\bar{X} = 73$	$\bar{X} = 99$	$\bar{X} = 70$		
	$\bar{X}_{\text{std}} = 71.5$	$\bar{X}_2 = 89.5$	$\bar{X}_3 = 69$		$\bar{\bar{X}} = 76.67$

The six combinations of rows and columns are called cells. The six cell means, two row means, three column means, and the grand mean are provided. In two-way ANOVA, we want to know if there is a main effect for any of the factors, or, in other words, if there are differences in the means of the levels of one factor averaged across the levels of the other factor. In our example, there are

Fig. 1 Hypothetical scores in a 3×2 factorial study of the effects of teaching method and time spent teaching on mathematics achievement scores.

two possible main effects and the essential questions can be phrased as: (1) Is there an overall influence of teaching method (for both the 45 min and 90 min conditions), and (2) is there an overall influence of time devoted to teaching (across all three teaching methods)?

There is an equally, if not more, important question that we can examine with a factorial design: Is there an interaction effect—are the differences among the levels of one factor the same for all levels of the other factor? To better understand this, let us first look at the results of our study in graph form (Fig. 1).

In our hypothetical study, if an increase in time spent teaching mathematics had an equal effect for all three teaching methods, the three lines would be parallel. A sizable gap between the lines indicates a possible main effect for teaching method. In our graph, we see evidence for a main effect, but the difference between method 2 and the other two teaching methods depends on the amount of time used in the classroom. Method 2 results in moderately better mathematics achievement scores when used for 45 min per day, but dramatically better scores when students are taught mathematics by this method for 90 min per day. If there had been a main effect for teaching method (method 2 better than the other two) without an interaction effect, the differences between method 2 and the others would have been the same for both levels of the other factor (teaching time per day). In other words, the lines in Fig. 1, would be approximately parallel to one another. A significant interaction effect tells us that before we can interpret the effects of a factor, we must examine that factor at each level of the other factor. This will, of course, involve examining cell means. Three-factor experimental designs (e.g., teaching method $\times$ time spent teaching $\times$ gender) and even higher-order designs are possible, but interpretation of interaction effects becomes more difficult.

When calculating two-way ANOVA, SS_{total} is partitioned into four parts. SS_{wc} (within cell) is the equivalent of SS_{w} (within groups) in the one-factor design. SS_{bet} is split into three parts: SS_{rows} , SS_{columns} , and $SS_{\text{rows} \times \text{columns}}$. To see how to calculate two-way ANOVA, see King et al. (2018). In our example, we obtain a significant effect for rows [$F(1,42) = 30.78$, $p < 0.001$], columns [$F(2,42) = 80.21$, $p < 0.001$], and rows $\times$ columns interaction [$F(2,42) = 14.59$, $p < 0.001$]. As at least one of our main effects was statistically significant, we may now conduct a *post hoc* test to see which levels differed from the others (e.g., method 2 vs. the other two).

As we learned above, MANOVA can be used for one-way ANOVA—both independent groups and repeated-measures designs. Not surprisingly, it can also be extended to two-way designs. Using the current example, we could have a 3×2 MANOVA where we measure not only mathematics achievement, but also math self-efficacy. This would allow us to test for both main effects (teaching method and time spent teaching) and a potential interaction effect but on two dependent variables simultaneously.

Planned comparisons

When conducting any statistical test one wants the test to have considerable power, that is, a high probability of rejecting a false null hypothesis. *Post hoc* tests allow us to make all possible pairwise comparisons, but to protect us from making Type I errors, the differences between means must be large enough to be declared statistically significant. If one's study is exploratory in nature, then ANOVA is a very good statistical test. However, if one knows in advance of conducting a study which comparisons are important

to him or her, one should use planned (*a priori*) comparisons in place of ANOVA and *post hoc* comparisons (Rosnow and Rosenthal, 1989; Wilkinson and The Task Force on Statistical Inference, 1999; Winer et al., 1991). To do so, one should conduct independent-groups *t* tests using s^2_w (calculated from all groups), but to protect against Type I errors, all the comparisons must be orthogonal (unique, with no overlap). When comparing k groups, there are only $k-1$ orthogonal comparisons. In our example, we might be interested in the two comparisons standard method versus (method 2 + method 3) and method 2 versus method 3. Unlike *post hoc* comparisons, one does not need a significant overall *F* in order to use planned comparisons. Even Ronald Fisher recognized the value of planned comparisons:

When the [*F*] test does not demonstrate significant differentiation, much caution should be used before claiming significance for special comparisons. Comparisons, which the experiment was designed to make, may, of course, be made without hesitation (Fisher, 1949: 57).

Introduction

The analysis of covariance (ANCOVA) is an inferential statistical method for analyzing experimental data that allows for the comparison of two or more group means while controlling for one or more covariates. As Fisher, who invented the procedure, explained, the analysis of covariance “combines the advantages and reconciles the requirements of the two very widely applicable procedures known as regression and analysis of variance” (1934, p. 269). ANCOVA improves upon the analysis of variance (ANOVA) in two key ways. First, by controlling for covariates that are correlated with the outcome, the ANCOVA test of treatment efficacy (i.e., difference in group means) is typically more powerful than the analogous ANOVA-based test. Second, in situations where random assignment fails to provide adequate balance on a confounding variable, or in cases where random assignment was not implemented, ANCOVA may be used to “control for” covariates by making linear adjustments to estimated group means that can reduce or remove bias due to confounding.

The use of ANCOVA to identify average treatment effects—either in the context of a well-implemented randomized experiment to reduce error variance or in a non-randomized study to control for confounding—requires assumptions, some of which are more likely to be tenable in practice than others. In modern usage, the meaning of ANCOVA is sometimes broadened to include nonlinear transformations of covariates or treatment by covariate interactions (cf. Huitema, 2011). Our focus herein, however, will be on the use of ANCOVA in the classical sense, as a method used to test for constant treatment effects assuming linear functional forms.

Multivariate analysis of variance (MANOVA) extends ANOVA to allow for simultaneous testing for treatment effects in the presence of multiple outcome variables. For correlated outcome variables, MANOVA may provide substantially better power to detect effects than the associated univariate ANOVAs. This same rationale holds when also controlling for one or more covariates via multivariate ANCOVA (MANCOVA); thus, we find reason to recommend MANCOVA for scenarios involving multiple correlated outcome variables.

The remainder of this chapter is organized as follows. In the next section we briefly define some key terms and describe the general linear *F* test, which is used to construct hypothesis tests in ANOVA and ANCOVA. In the third section, because central concepts in ANCOVA are most meaningful when compared against analogous concepts in ANOVA, we describe the univariate one-way ANOVA model, give a data example, and discuss pairwise comparisons of group means through contrast testing. We present the univariate ANCOVA model in **Univariate ANCOVA** section, where we examine the omnibus *F* statistic in relation to ANOVA, give a data example, describe adjusted group means, and discuss the role of covariate balance in ANCOVA adjustment. We then follow a similar structure for the multivariate procedures, introducing MANOVA first and following with MANCOVA and a data demonstration. We conclude with some discussion.

The general linear *F* test

Consider a simple linear regression model for outcome *Y* and predictor *X*,

$$Y_i = \beta_0 + \beta_1 X_i + \varepsilon_i \quad (1)$$

Fig. 1 Scatterplot of baseline and outcome data with fitted regression line and residuals.

where errors are independent and identically (iid) normally distributed with mean zero and constant variance; i.e., $\varepsilon_i \sim N(0, \sigma^2)$. When data are used to estimate the parameters of the model, the resulting function may be used to predict the mean of the outcome, Y , conditional on the values of the predictor, X . The outputs from this function are called *predictions* or *fitted values*, and the fitted value for the i th unit is denoted as $\hat{Y}_i$ as follows,

$$E[Y_i|x_i] = \hat{Y}_i = \hat{\beta}_0 + \hat{\beta}_1 x_i \quad (2)$$

where $\hat{\beta}_0$ and $\hat{\beta}_1$ are, respectively, estimates for β_0 and β_1 . The *residual* for participant i , e_i , is defined as the difference in observed and predicted values; that is, $e_i = Y_i - \hat{Y}_i$; see Fig. 1.

Sums of squared residuals may be used to create measures of model fit. In particular, sums of squared residuals give a quantitative summary of variation leftover (i.e., not explained) by the model. The *general linear F test* provides a framework for constructing hypothesis tests by comparing regression models using sums of squares (SS). As an example, to test $H_0: \beta_1 = 0$ for the simple regression model in Eq. (1), a *restricted* model is specified in which the parameter to be tested (or parameters, if a joint test is desired) is fixed to the hypothesized value. Here the restricted model would be $Y_i = \beta_0 + \varepsilon_i$. The general linear F statistic is defined as

$$F = \frac{(SS_R - SS_F)/(df_R - df_F)}{SS_F/df_F} \quad (3)$$

where SS_R and SS_F are the sums of squared residuals, and df_R and df_F are degrees of freedom, for the restricted and full models, respectively. If errors $\varepsilon_i \sim N(0, \sigma^2)$, then the statistic F will follow an F distribution under the null hypothesis with $df_R - df_F$ numerator and df_F denominator degrees of freedom.¹

Univariate ANOVA

It is helpful to use the analysis of variance (ANOVA) as a starting point from which to describe the ANCOVA model. For a single-factor experiment, the one-way ANOVA model may be described as follows,

$$Y_{ij} = \mu + \alpha_j + \varepsilon_{ij} \quad (4)$$

where,

- Y_{ij} is the outcome variable for participant i in group j ,
- μ is the unweighted average of group means,
- α_j is the treatment effect (i.e., $\mu_j - \mu$) for the j th group, and
- ε_{ij} is idiosyncratic (random) error for participant i in level j .

The ε_{ij} are assumed to be independent $N(0, \sigma^2)$ random variables. To uniquely define model parameters, a constraint is typically imposed such that the treatment effects add to zero, $\sum_{j=1}^a \alpha_j = 0$.² The one-way ANOVA model assumes that any systematic variability in the outcome is solely due to the treatment factor groupings, and each α_j represents the j th group's deviation from the overall

¹See Maxwell et al. (2018) and Neter et al. (1990) for texts that build up test statistics for ANOVA and ANCOVA via model comparisons using the general linear F test.

²Another possibility is to require a *weighted* sum of the to be zero. In that case, μ is a weighted average of group means. For a useful discussion of weighting schemes and implications, see Neter et al. (1990, pp. 554–556).

population mean, μ . Suppose there are a groups in total with n_j participants in the j th group. The omnibus null hypothesis for the one-way ANOVA is that all treatment effects are identically equal to zero; that is,

$$H_0 : \alpha_1 = \alpha_2 = \cdots = \alpha_a = 0$$

Let $\bar{y}$ and $\bar{y}_j$ be estimates of the overall mean and group j mean, respectively. Full and restricted models and least squares estimators are shown in Table 1. The sums of squares (SS) decomposition for ANOVA is motivated by the model in Eq. (4). After subtracting the mean μ from both sides, Eq. (4) may be expressed as follows,

$$Y_{ij} - \mu = \alpha_j + \varepsilon_{ij} \quad (5)$$

and with sample analogs as

$$(y_{ij} - \bar{y}) = (\bar{y}_j - \bar{y}) + (y_{ij} - \bar{y}_j) \quad (6)$$

The three terms in parentheses in Eq. (6) are referred to as *deviations*. Squaring both sides, canceling out the middle term on the right hand side because $\sum_{i=1}^{n_j} (y_{ij} - \bar{y}_j) = 0$, and summing over all i and j leads to the sums of squares decomposition for one-way ANOVA; see Eq. (7). Note the sum of squares “total” does not represent the total squared variation in the outcome variable because the mean has been subtracted off the left hand side of the equation. Thus, SST is typically referred to as “corrected for the mean”.

$$\begin{aligned} SS_{T; \text{total (corrected)}} &= SS_{B; \text{between}} + SS_{W; \text{within}} \\ \sum_{j=1}^a \sum_{i=1}^{n_j} (y_{ij} - \bar{y})^2 &= \sum_{j=1}^a n_j (\bar{y}_j - \bar{y})^2 + \sum_{j=1}^a \sum_{i=1}^{n_j} (y_{ij} - \bar{y}_j)^2 \end{aligned} \quad (7)$$

After substitution and some algebra, the F statistic for the one-way ANOVA omnibus null hypothesis may be written in terms of SS_B and SS_W as follows,

$$F = \frac{(SS_R - SS_F)/(df_R - df_F)}{SS_F/df_F} = \frac{SS_B/(a - 1)}{SS_W/(N - a)} \quad (8)$$

where N is the total number of participants. If $\varepsilon_{ij} \stackrel{iid}{\sim} N(0, \sigma^2)$, the F statistic will follow an F distribution with $a - 1$ numerator and $N - a$ denominator degrees of freedom under the null hypothesis.

Data demonstration

Consider a hypothetical experiment in which a total of $N = 15$ participants were randomly assigned to three groups (two treatments and a control) with equal frequency (i.e., $n_1 = n_2 = n_3 = 5$). All participants were measured at baseline on a variable known to be positively correlated with the outcome. The one-way ANOVA restricted model assigns predicted values to participants based on the overall mean of the outcome variable, regardless of group membership; whereas, the full model assigns a predicted value to each participant based on their group mean. The left and right panels of Fig. 2 depict the data by group along with restricted and full models for the one-way ANOVA omnibus null hypothesis along with dotted lines tracing residuals that contribute to SS_R and SS_F .

ANOVA results are often displayed in tabular form as in Table 2, which reveals that $SS_B = 1890.1$ and $SS_W = 3710.0$. The mean squares of 945.1 and 309.8 represent, respectively, the numerator and denominator of the F statistic. Their quotient is 3.06 which, when compared with an F distribution with $3 - 1 = 2$ numerator and $15 - 3 = 12$ denominator df yields a p value of 0.084.

Fig. 2 ANOVA restricted (left panel) and full (right panel) model fits and residuals.

Table 1 Full and restricted models, parameters, and least-squares estimators for the one-way ANOVA omnibus test.

ANOVA	Model	Parameters	Least-squares estimators
Full	$Y_{ij} = \mu + \alpha_j + \varepsilon_{ij}$	μ $\alpha_j, \alpha_2, \dots, \alpha_J$	$\hat{\mu} = \bar{y}$ $\hat{\alpha}_j = \bar{y}_j - \bar{y}$
Restricted	$Y_{ij} = \mu + \varepsilon_{ij}$	μ	$\hat{\mu} = \bar{y}$

Comparing group means

A rejection of the omnibus test null hypothesis signals that at least one of the treatments had an effect, or, equivalently, that at least one pair of group means differ. Questions about which group means differ and by how much may be addressed by estimating and testing contrasts. A *contrast* is a linear combination of the group means such that the coefficients add up to 0. That is, ψ is a contrast if it may be written as follows,

$$\psi = c_1\mu_1 + c_2\mu_2 + \dots + c_a\mu_a = \sum_{j=1}^a c_j\mu_j \quad (9)$$

where $\sum_j c_j = 0$. Sample group means may be substituted to obtain an estimate,

$$\hat{\psi} = c_1\bar{y}_1 + c_2\bar{y}_2 + \dots + c_a\bar{y}_a = \sum_{j=1}^a c_j\bar{y}_j \quad (10)$$

and null hypotheses of the form $H_0 : \psi = 0$ may be tested by constructing an F statistic,

$$F_\psi = \frac{\hat{\psi}^2 / \sum_{j=1}^a \left(\frac{c_j}{n_j} \right)}{MS_W} \quad (11)$$

The statistic F_ψ will follow an F distribution under the null hypothesis with 1 numerator and $df_F = N - a$ denominator degrees of freedom. Contrasts for pairwise comparisons of means for treatment groups A and B and the control group, along with estimates, F statistics, and p -values, are given in [Table 3](#). The estimated group mean differences of 19.4, 26.2, and 7.2 may be directly observed as vertical distances between prediction lines in the full ANOVA model depicted in the right panel of [Fig. 2](#).

Univariate ANCOVA

The one-way ANCOVA model extends ANOVA by adding one or more numeric predictors (i.e., covariates). With a single covariate, X_{ij} , the ANCOVA model may be written as follows,

$$Y_{ij} = \mu + \alpha_j + \beta_1 X_{ij} + \varepsilon_{ij} \quad (12)$$

where β_1 is the slope that quantifies the strength of the linear relationship between the covariate, X , and the outcome, Y , and other parameters are defined as in [Eq. \(4\)](#).

Table 3 Table of contrasts, estimates, F statistics, and adjusted p -values for pairwise comparisons of group means.

Comparison	Ψ	$\hat{\psi}$	F	p
A vs. B	$1\mu_A - 1\mu_B + 0\mu_C$	19.4	3.03	0.23
A vs. control	$1\mu_A + 0\mu_B - 1\mu_C$	26.6	5.71	0.08
B vs. control	$0\mu_A + 1\mu_B - 1\mu_C$	7.2	0.42	0.80

Note. p -values are adjusted via Tukey's HSD for a family of three pairwise comparisons.

Table 4 Full and restricted models, parameters, and least-squares estimators for the one-way ANCOVA omnibus test for a model with one covariate.

ANCOVA	Model	Parameters	Least-squares estimator
Full	$Y_{ij} = \mu + \alpha_j + \beta_1 X_{ij} + \varepsilon_{ij}$	μ $\alpha_1, \alpha_2, \dots, \alpha_a$ β_1	$\hat{\mu} + \hat{\alpha}_j = \bar{y}_j - b_W \bar{x}_j$ $\hat{\beta}_1 = b_W$
Restricted	$Y_{ij} = \mu + \beta_1 X_{ij} + \varepsilon_{ij}$	μ β_1	$\hat{\mu} = \bar{y} - b_T \bar{x}$ $\hat{\beta}_1 = b_T$

The least squares estimator for coefficient β_1 under the restricted ANCOVA model, b_T , is referred to as the total or overall regression slope because it ignores group membership:

$$b_T = \frac{\sum_{j=1}^a \sum_{i=1}^{n_j} (x_{ij} - \bar{x})(y_{ij} - \bar{y})}{\sum_{j=1}^a \sum_{i=1}^{n_j} (x_{ij} - \bar{x})^2} \quad (13)$$

The least squares estimator for β_1 under the full ANCOVA model, b_W , is referred to as the pooled within-group regression slope because it estimates a single slope by pooling the numerator and denominator components that would have contributed to the within-group slopes had they been estimated separately³:

$$b_W = \frac{\sum_{j=1}^a \sum_{i=1}^{n_j} (x_{ij} - \bar{x}_j)(y_{ij} - \bar{y}_j)}{\sum_{j=1}^a \sum_{i=1}^{n_j} (x_{ij} - \bar{x}_j)^2} \quad (14)$$

As with the ANOVA model, the F statistic for testing the omnibus null hypothesis, $H_0 : \alpha_1 = \alpha_2 = \dots = \alpha_j$, under the ANCOVA model may be built up by making model comparisons under the general linear F framework. In particular,

$$F = \frac{\left(SS_B - \left[b_T^2 \sum_{j=1}^a \sum_{i=1}^{n_j} (x_{ij} - \bar{x})^2 - b_W^2 \sum_{j=1}^a \sum_{i=1}^{n_j} (x_{ij} - \bar{x}_j)^2 \right] \right) / (a - 1)}{\left(SS_W - b_W^2 \sum_{j=1}^a \sum_{i=1}^{n_j} (x_{ij} - \bar{x}_j)^2 \right) / (N - a - 1)} \quad (15)$$

$$= \frac{SS_{B(\text{adj})} / (a - 1)}{SS_{W(\text{adj})} / (N - a - 1)} \quad (16)$$

where $SS_{B(\text{adj})}$ and $SS_{W(\text{adj})}$ are sums of squared residuals that have been *adjusted* for the linear regression of the outcome on the baseline covariate. The value of $SS_{B(\text{adj})}$ may be larger or smaller than the unadjusted (ANOVA) value of SS_B ; however, when participants are randomly assigned to groups, the value of $SS_{B(\text{adj})}$ will, on average, be identical to the unadjusted value of SS_B .

In contrast, $SS_{W(\text{adj})}$ will always be less than or equal to SS_W due to the subtraction of a non-negative term, which removes within-group variability due to the linear relationship between the outcome, Y , and the covariate, X , from the residuals. The stronger the linear relationship between X and Y within groups, the greater the reduction in $SS_{W(\text{adj})}$ relative to SS_W . If the covariate and outcome have no linear relationship in the sample, the value of b_W^2 will be zero, and the inclusion of the covariate will have no effect on SS_W . Note that the denominator df , $N - a - 1$, is decreased by one relative to ANOVA because one additional parameter, β_1 , is included in the ANCOVA model. Full and restricted models and least squares estimators for the one-way ANCOVA model are given in [Table 4](#).

Data demonstration

The left and right panels of [Fig. 3](#) depict the restricted and full models for the one-way ANCOVA omnibus null hypothesis along with dotted lines tracing residuals. Though it may be difficult to discern from the plot, the slope of the regression line in the left panel ($b_T = 3.51$) is slightly less steep than the three identical regression slopes in the right panel ($b_W = 3.71$).

³See [Wildt and Ahtola \(1978\)](#) for derivations of b_T and b_W .

Fig. 3 ANCOVA restricted (left panel) and full (right panel) model fits and residuals.

Table 5 ANOVA output table for the ANCOVA model; SS = sum of squares; MS = mean squares; df = degrees of freedom.

Source	SS	df	MS	F	p
Between (adjusted)	1990.3	2	995.2	5.56	0.021
Covariate	1740.6	1	1740.6	9.72	0.010

ANCOVA results are displayed in [Table 5](#). It is of interest to compare results with those of the ANOVA, shown in [Table 2](#). Here we see that $SS_{B(\text{adj})} = 1990.3$ as compared with $SS_B = 1890.1$. That this value changed by a small amount, only about 5% here, is expected because participants were randomly assigned to treatment groups and, therefore, were well-balanced on the baseline covariate. The change in within-subject variation is more drastic: $SS_{W(\text{adj})} = 1969.4$ as compared with $SS_W = 3710.0$. This large reduction of approximately 50% is also expected due to the strong positive linear relationship between the covariate and the outcome, and can be seen graphically by noting that the residuals in the right panel of [Fig. 3](#) (ANCOVA full model) are substantially smaller, on average, than those in the right panel of [Fig. 2](#) (ANOVA full model).

The ANCOVA-based test of the omnibus null hypothesis ($F(2, 11) = 5.56$; $p = 0.021$) produced a larger F statistic and smaller p -value than the ANOVA-based test ($F(2, 12) = 3.06$; $p = 0.084$), largely due to the reduction in $SS_{W(\text{adj})}$ relative to SS_W . That is, accounting for the linear relationship between the covariate and the outcome carved away a large portion of the variation that had previously contributed to the error variance.

Adjusted group means

Estimated group means under the ANCOVA full model are no longer equal to observed sample group means; instead, they are conditional on the value of the covariate (or covariates, if more than one are included).

$$\begin{aligned} E[Y_{ij}|x_{ij}] &= \hat{\mu} + \hat{\alpha}_j + b_W x_{ij} \\ &= \bar{y}_j + b_W(\bar{x}_j - \bar{x}_{ij}) \end{aligned} \quad (17)$$

By conditioning on a single value of the covariate, ANCOVA allows us to assess what the impact of each treatment *would have been* had all the groups been centered at the same value on the covariate. For each group, $j = 1, \dots, a$, the *adjusted group mean*, $\bar{y}'_j$, is defined as the predicted mean of the outcome score given that the covariate is set to its overall mean, $\bar{x}$.

$$\bar{y}'_j = E[Y_{ij}|x_{ij} = \bar{x}] = \bar{y}_j + b_W(\bar{x}_j - \bar{x}) \quad (18)$$

Pairwise differences in adjusted group means, shown in [Table 6](#), may be visualized as vertical distances between regression lines in the right panel of [Fig. 3](#).

Covariate balance, overlap and ANCOVA adjustment

A covariate is said to be *balanced* with respect to the treatment groups if it is identically distributed across those groups. Covariate balance is expected in well-implemented randomized experiments because random assignment renders all covariates, X , statistically

Table 6 Table of contrasts for pairwise comparisons of adjusted group means.

Comparison	ψ	$\hat{\psi}$	F	p-value
A vs. B	$1\mu_A - 1\mu_B + 0\mu_C$	15.4	3.22	0.216
A vs. control	$1\mu_A + 0\mu_B - 1\mu_C$	28.2	11.08	0.017
B vs. control	$0\mu_A + 1\mu_B - 1\mu_C$	12.9	2.21	0.335

Note. p-values are adjusted via Tukey's HSD for a family of three pairwise comparisons.

**Fig. 4** A two-group experiment with baseline covariate balance (left panel) and imbalance (right panel).

independent of the treatment assignment, T ; that is, $X \perp T$. In non-randomized studies or when randomization becomes complicated by post-treatment factors such as differential attrition, covariates may be systematically imbalanced.⁴ When an important baseline covariate is imbalanced, adjustment via ANCOVA may cause unadjusted and adjusted group means and, hence, $SS_{B(adj)}$ and SS_B , to differ systematically. The direction of the difference depends on the severity of the imbalance and the magnitudes of b_T and b_W ; see the numerator of Eq. (15).

Consider the stylized diagrams in Fig. 4. The data in the left panel display good covariate balance at baseline, as evidenced by overlapping ranges of covariate values across groups and identical covariate group means (i.e., $\bar{x}_1 = \bar{x}_2 = \bar{x}$). Despite the strong positive linear relationship between the baseline covariate and the outcome, covariate adjustment will make no systematic difference to the estimates of treatment effect in cases of good balance; note that $\bar{y}'_2 - \bar{y}'_1 = \bar{y}_2 - \bar{y}_1$ in the left panel of Fig. 4.

Data in the right panel display covariate imbalance at baseline. If X and T were truly independent, we would not expect such drastic lack of overlap in covariate values across groups and differing covariate group means (i.e., $\bar{x}_1 \neq \bar{x}_2$). In this case, the covariate X appears to be a confounding variable because it is associated both with the group assignment and with the outcome variable. If the assumed linear functional forms, as specified in Eq. (12), are correct, estimates based on the adjusted means will remove confounding bias due to the covariate from effect estimates; note that $\bar{y}'_2 - \bar{y}'_1 < \bar{y}_2 - \bar{y}_1$. The trouble is that when covariate imbalance leads to lack of covariate overlap, assumptions about correct model specification must be made based on extrapolation (i.e., in the absence of data), which is not advised.

Although lack of overlap is easy to spot when controlling for only one covariate, it is more difficult to visualize as more covariates are included. One solution is to estimate the propensity score, which serves as a unidimensional balance proxy for the full set of observed covariates (Rosenbaum and Rubin, 1983). There are a number of resources that provide guidance on best practices for the use of propensity scores for checking overlap (see, e.g., Keller and Tipton, 2016; Schafer and Kang, 2008; and Steiner and Cook, 2013).

Assumptions and limitations

The assumptions required for valid statistical inference in ANCOVA may be summarized succinctly by the statement, $\varepsilon_{ij} \stackrel{iid}{\sim} N(0, \sigma^2)$.

1. *Errors are statistically independent.* That is, after accounting for the variation explained by the covariates and by group membership, residual variations are assumed to be independent. This assumption could be violated if, for example, participants were repeatedly measured. In that case, each participant's set of measurements would likely be more highly correlated with one another than with those of other participants, even after controlling for fixed effects in the model. It is typically not possible to

⁴While it is possible that a well-implemented randomized experiment may result in poor baseline covariate balance due to an unlucky randomization, this becomes less and less likely as sample sizes increase. For small to moderate samples, where chance imbalances are more likely, rerandomization (Morgan and Rubin, 2014; Zhou et al., 2018) may be used to ensure a minimum level of balance is achieved.

test the independence assumption with data; instead, logical arguments based on how the data were collected must be made to defend it.

2. *Errors are normally distributed with mean 0 and constant variance.* For any combination of covariate values and/or group indicators, outcome data are assumed to have been generated from identical normal distributions, each with mean 0 and constant variance, σ^2 .
 - (a) *Linearity.* The assumption of zero conditional mean implies that the functional form given in Eq. (12) is correctly specified. This can go wrong if the true relationship between the covariate and the outcome is nonlinear or if there is effect modification (i.e., the magnitudes and/or directions of treatment effects vary with the values of a covariate).
 - (b) *Constant variance.* When group sizes are equal, or nearly so, ANCOVA-based tests are generally robust to violations of the constant variance assumption. For unbalanced group size pairings, however, heterogeneous variances may cause problematic departures from expected type I error rates. The Welch-Satterthwaite correction is recommended for such cases because it maintains nominal type I error rates in the face of group variance heterogeneity and still is quite powerful relative to alternatives (Tomarken and Serlin, 1986).
 - (c) *Normal distribution.* The ANCOVA omnibus null hypothesis test is somewhat robust to non-normally distributed residuals, in particular as sample sizes grow larger. Violation of the distributional assumption may invalidate the nominal type I error rate for smaller samples, especially when coupled with unbalanced group sizes.

When verifying the tenability of the latter three assumptions with data, we recommend using a multifaceted approach that includes graphical exploration, estimation of relevant effect sizes, and the use of hypothesis tests. Other issues such as multicollinearity and influential observations can have an impact on the stability of results. For more detailed discussions on checking assumptions see, e.g., Keppel and Wickens (2004), Huitema (2011), Maxwell et al. (2018), and Fox (2008).

Multivariate ANOVA

Multivariate analysis of variance (MANOVA) is a generalization of ANOVA to multiple dependent variables (DVs). Paralleling Eq. (4), the MANOVA model is:

$$Y_{ij} = \mu + \alpha_j + \varepsilon_{ij}, \quad i = 1, \dots, n_j, j = 1, \dots, a \quad (19)$$

where each term is now a p -dimensional vector, and the errors ε_{ij} are assumed to be independent multivariate normal $N_p(0, \Sigma)$ variables. As in the univariate case, the treatment effects may be parameterized to satisfy $\sum_{j=1}^a \alpha_j = 0$. Note that each component of the observed vector Y_{ij} satisfies the univariate model 3 and that the error components are correlated, but the overall covariance matrix Σ is the same for all groups.

The overall omnibus null hypothesis to be tested is that the vector of treatment effects for each outcome variable is identical across all groups:

$$H_0 : \alpha_1 = \alpha_2 = \dots = \alpha_a = 0$$

Furthermore, the decomposition in Eq. (6) still holds in its multivariate version:

$$(y_{ij} - \bar{y}) = (\bar{y}_j - \bar{y}) + (y_{ij} - \bar{y}_j) \quad (20)$$

Since each term in Eq. (20) is a vector, it can't simply be squared; instead outer products are used, and the resulting equation consists of *matrices* of sums of squares and cross products (SSCP):

$$\text{SSCP}_{T; \text{ total (corrected)}} = \text{SSCP}_{B; \text{ between}} + \text{SSCP}_{W; \text{ within}} \\ \sum_{j=1}^a \sum_{i=1}^{n_j} (y_{ij} - \bar{y})(y_{ij} - \bar{y})' = \sum_{j=1}^a n_j (\bar{y}_j - \bar{y})(\bar{y}_j - \bar{y})' + \sum_{j=1}^a \sum_{i=1}^{n_j} (y_{ij} - \bar{y}_j)(y_{ij} - \bar{y}_j)' \quad (21)$$

The following matrices are multivariate analogs to SS_B and SS_W :

$$B = \sum_{j=1}^a n_j (\bar{y}_j - \bar{y})(\bar{y}_j - \bar{y})' \quad (22)$$

$$W = \sum_{j=1}^a \sum_{i=1}^{n_j} (y_{ij} - \bar{y}_j)(y_{ij} - \bar{y}_j)' \quad (23)$$

In the univariate case the sum of squares SS_B and SS_W are independently distributed with χ^2 distributions, and in the multivariate case B and W have independent Wishart distributions. To test the overall omnibus null hypothesis, a measure of how *large* the matrices B and W are is needed. There is *no unique* way to extend the F -test from Eq. (8) to the multivariate case. Different researchers have proposed different multivariate analogies to the F -statistic. One of the most commonly used is Wilks' (1932) Lambda statistic:

$$\Lambda = \frac{\det(W)}{\det(B + W)} \quad (24)$$

As Wilks' Λ is a ratio of the determinants of two Wishart distributed matrices, exact results for its distribution are not available in general, but there exist relationships to the F distribution for some special cases of p and a , or an asymptotic χ^2 approximation due to Bartlett (1938). Essentially, Wilks' Λ arises from the likelihood ratio principle and so does its asymptotic behavior. Note that more separation among the groups will drive the W matrix closer to 0; therefore, H_0 is rejected for *small* values of Λ . Wilks' Λ can also be written as $\Lambda = \frac{1}{\det(I + W^{-1}B)}$, and consequently, using the eigenvalues $\lambda_1, \dots, \lambda_r$ of the matrix $W^{-1}B$, where $r = \text{rank}(B)$ as:

$$\Lambda = \prod_{i=1}^r \frac{1}{1 + \lambda_i} \quad (25)$$

As groups become more separated, W becomes closer to being a singular matrix, so the eigenvalues grow larger. Other approaches for testing H_0 due to Pillai, Lawley-Hotelling and Roy are all based on the same eigenvalues but use them in a different way. For example, Pillai's trace statistic is defined as

$$V = \text{tr}((W + B)^{-1}B) = \sum_{i=1}^r \frac{\lambda_i}{1 + \lambda_i} \quad (26)$$

and H_0 is rejected for *large* values of V . For very large samples, all four criteria are indistinguishable. For small to moderate sample sizes, some simulation-based evidence suggests that Pillai's trace is more robust to non-normality (Johnson and Wichern, 2007, p. 336).

If the multivariate omnibus null hypothesis is rejected, it is typically of interest to know which variables contributed to the rejection of the null hypothesis and which did not. Rencher and Christensen (2012, p. 195) argue that follow-up univariate ANOVA F -tests do not change the overall nominal significance level, provided that they are performed *only after rejection* of the MANOVA null hypothesis. However, this does not mean that these univariate F -tests might not suffer from inflated Type II error rates (i.e., lack of power).

This is illustrated in Fig. 5, where the true population distribution is a bivariate normal with mean $(0, 0)$, variances equal to 2 and 1, and a covariance equal to 1, which results in a high correlation of $\sqrt{2}/2 \approx 0.71$. This can be thought of as the distribution of the difference between two groups, which under the null hypothesis should have mean $(0, 0)$. The outermost red ellipse corresponds to the 95% contour of the distribution, which demarcates the acceptance and rejection regions for the multivariate null hypothesis. The shaded rectangular area is the Cartesian product of the acceptance regions of the two univariate tests.

The dot represents a potential sample with mean $(2, -1)$, which is not an unusual data point if looking at each variable separately, as shown by the fact that the point is inside the rectangle corresponding to the Bonferroni adjusted simultaneous 95% CIs for the univariate tests. Such data would result in rejection of the *multivariate* hypothesis because under the null hypothesis it is very unlikely to observe data with a large positive Y_1 mean together with a negative Y_2 mean. However, neither of the follow-up univariate hypotheses would be rejected.

Fig. 5 A bivariate normal distribution with correlation 0.71. The area outside the red ellipse represents the rejection region for the multivariate omnibus null hypothesis test. The area outside the shaded rectangle represents the Bonferroni-corrected rejection region for (either of the two) univariate omnibus null hypothesis tests. For the sample mean vector $\bar{y}$, the multivariate test rejects while the univariate tests do not. Neither $y_1 = 2$ nor $y_2 = -1$ is an unlikely observation when *taken alone*, however, given the correlation between Y_1 and Y_2 , they are quite unlikely to have been observed *together*.

Multivariate ANCOVA

Multivariate analysis of covariance (MANCOVA) is a combination of the MANOVA model with a multivariate regression model with one or more predictors. The inclusion of these covariates leads to *noise reduction* in the sense that the variance associated with the covariates is removed from the error variance, thus providing a more powerful test for the difference between the groups. The model with a single covariate may be written as follows,

$$Y_{ij} = \mu + \alpha_j + \beta_1 x_i + \varepsilon_{ij}, \quad i = 1, \dots, n_j, j = 1, \dots, a \quad (27)$$

where each term is a $p \times 1$ vector. The general case is easier to write in matrix notation,

$$\underset{n \times p}{Y} = \underset{n \times a \times p}{Z} \underset{n \times a}{\alpha} + \underset{n \times b \times p}{X} \underset{n \times b}{\beta} + \underset{n \times p}{E} \quad (28)$$

where Z is the MANOVA design matrix, and X is the multivariate regression matrix containing b covariates. The estimates of the coefficients are produced via standard multivariate regression formulas (see, e.g., [Timm, 2002](#), p. 226). For example, using the generalized inverse matrix $(Z'Z)^-$ for the case when the MANOVA is overparametrized,⁵ we have:

$$\hat{\alpha} = (Z'Z)^- Z' (Y - X\hat{\beta}) \quad (29)$$

Observe that this estimate of the group effects is adjusted by the residual from a regression on the covariates.

To test hypotheses about the treatment effects, α , the standard approach is to obtain the “within” matrix (now called the *residual matrix*) W_{full} from the full model in [Eq. \(28\)](#) and the residual matrix $W_{reduced}$ from the model under the null hypothesis, and then proceed the same way as in the MANOVA hypothesis, using the eigenvalues of $W_{full}^{-1}(W_{full} - W_{reduced})$. To summarize, the MANCOVA test enjoys the benefits of both MANOVA (i.e., increased power for rejecting the omnibus test with correlated outcomes) and ANCOVA (i.e., reduction of within-groups error terms via regression).

Assumptions and limitations

Significance tests for MANOVA, MANCOVA, and many other multivariate statistical analyses are based on the assumption that the data are multivariate normal. More specifically, the error matrix E in [Eq. \(28\)](#) is assumed to contain on each row independent vectors which are distributed $N_p(0, \Sigma)$.

1. *Row vectors are independent.* This assumption is analogous to the univariate case with exception that the observations associated with the same participant are assumed to be correlated as specified in Σ .
2. *Error vectors are multivariate normal with zero mean vector and constant covariance matrix.*
 - (a) *Linearity.* In line with the univariate case, the relationships between covariates and outcome variables are assumed to be correctly specified.
 - (b) *Constant covariance matrix.* The assumption that each error vector is distributed $N_p(0, \Sigma)$ implies identical covariance matrices. This assumption is the multivariate analog to the univariate assumption of constant variance. The assumption may be tested with Box’s M test, though the test is sensitive to violations of other assumptions such as multivariate normality.
 - (c) *Multivariate normal distribution.* Multivariate normality implies that each outcome variable must be normally distributed, which can be tested with a number of tests such as Shapiro-Wilks, Anderson-Darling or Kolmogorov-Smirnov, as well as graphs such as a Q-Q plot. However, multivariate normality is a stronger assumption than individual univariate normality, and there are multivariate tests available in many software packages such as Mardia’s test and the Cox-Small test. [Mardia \(1971\)](#) argues that reasonably large sample sizes in each group ensure robustness and mitigates the need for extensive testing, though [Rencher and Christensen \(2012, p. 210\)](#) suggest checking for gross violations.

MANOVA and MANCOVA procedures are sensitive to outliers. Thus, it is recommended that tests for outliers are performed with any MANOVA and MANCOVA analysis. For more discussion of assumptions and their implications see, e.g., [Rencher and Christensen \(2012\)](#), [Johnson and Wichern \(2007\)](#) and [Tabachnick and Fidell \(2013\)](#).

Data demonstration

[Woodworth et al. \(2017\)](#) replicated a randomized efficacy study of three web-based positive psychology interventions and a control condition, and [Woodworth et al. \(2018\)](#) made the data publicly available. Participants assigned to the *gratitude* condition were asked to send a letter of gratitude to someone deserving in their life. Participants assigned to the *three good things* condition were asked to write down three good things that happened each day for a week. Participants assigned to the *signature strengths* condition completed a survey to assess character strengths and were asked to use one of their top five strengths each day for a week. Participants in the comparison group were asked to write about early memories each day for a week.

⁵Following [Timm \(2002\)](#), we use the superscript $-$ to denote the generalized inverse.

Fig. 6 Pretest and posttest scores on two dependent variables for the data demonstration; note the lack of balance across intervention group means at baseline.

Of interest is the effect of the intervention type ($a = 4$ groups) on the depression and happiness index scores ($p = 2$ DVs, correlated at -0.76). For this analysis we focus on the 147 participants who completed baseline and posttest measures; see Fig. 6. Neither Wilks nor Pillai MANOVA omnibus tests are significant ($p = 0.28$). A follow-up analysis with univariate F -tests on each of the DVs separately agrees with this result. Running a MANCOVA, controlling for baseline scores as covariates, also results in a nonsignificant omnibus test result ($p = 0.45$) via both Wilks and Pillai. The error matrices for the MANOVA and MANCOVA are:

$$W_{\text{MANOVA}} = \begin{pmatrix} 17736.79 & -15240.07 \\ -15240.07 & 22637.71 \end{pmatrix}, W_{\text{MANCOVA}} = \begin{pmatrix} 8458.66 & -5233.99 \\ -5233.99 & 7714.14 \end{pmatrix}$$

As expected, adjusting for baseline scores reduced important components of the error variance matrix. It is instructive to note that $\det(W_{\text{MANCOVA}}) = 3.8 \times 10^7$ is 4.5 times smaller than $\det(W_{\text{MANOVA}}) = 1.7 \times 10^8$. A similar comparison of the “Between” matrices (for formulas see Timm, 2002, p. 227), yields

$$B_{\text{MANOVA}} = \begin{pmatrix} 724.04 & -525.16 \\ -525.16 & 481.89 \end{pmatrix}, B_{\text{MANCOVA}} = \begin{pmatrix} 216.39 & -23.68 \\ -23.68 & 18.7 \end{pmatrix}$$

In general, for randomized experiments, we do not expect to see large differences in the MANOVA and MANCOVA covariate-adjusted between matrices. In this example, however, the determinant of the between matrix decreased by a factor of almost 21. The explanation for this large reduction in the magnitudes of the components of the between matrix is the lack of baseline balance in the analytic sample, perhaps due to post-randomization attrition. MANOVA fails to account for the baseline differences and attributes all outcome variation to the treatment. Whereas, with MANCOVA, the baseline variation in outcomes across treatments is accounted for and, thus, $\det(B)$ is substantially smaller. Note that we use these data to demonstrate the mechanics of the multivariate procedures. We have skipped over important details such as the verification of the tenability of assumptions and the reporting of and interpretation of results in context that should not be neglected in practice.

Discussion

Random assignment leads to covariate balance, which renders both ANOVA and ANCOVA-based estimators of effects unbiased (see the left panel of Fig. 4). The purpose of making ANCOVA adjustments with randomized experimental data is to reduce error variance, which leads to more precise estimates and more powerful tests. With observational data, ANCOVA may still be useful in reducing error variance, but it also is used for another purpose: to reduce bias due to confounding covariates.

The ANCOVA and MANCOVA models, as described in Eqs. (11) and (26), require (a) that relationships between covariates and outcomes are linear and (b) that treatment effects are constant across all covariate values. If either of these assumptions is violated, estimates based on adjusted means are no longer valid. Furthermore, because extrapolation is required when covariate imbalance leads to lack of overlap, the validity of the estimates may be quite sensitive to functional form misspecifications with observational data. That said, some empirical evidence suggests that in some cases the basic ANCOVA model can perform quite well with respect to bias reduction with observational data (Shadish et al., 2008); however, simulation evidence suggests that when functional form assumptions are violated, performance may be substantially improved by allowing for more flexible modeling, for example, by including covariate by treatment interaction terms to handle non-constant treatment effects (Schafer and Kang, 2008).

There is a rich and expanding literature on alternatives to ANCOVA for effect estimation in observational study settings in the causal inference literature; some of these approaches are reviewed in Schafer and Kang (2008). In recent years, a number of machine learning alternatives to ANCOVA for causal effect estimation with observational data have been proposed. These newer methods lack the simplicity and interpretability of ANCOVA but benefit from algorithmic handling of nonlinearities and interactions in their

naive implementations. Bayesian additive regression trees (Hill et al., 2011) and targeted maximum likelihood estimation (TMLE; van der Laan and Gruber, 2010) are two examples that have performed well in data competitions (Dorie et al., 2019). Furthermore, a number of new methods have been proposed for explicitly detecting and estimating causal effects in the presence of treatment effect heterogeneity. A special issue in the journal *Observational Studies* (Volume 5, Issue 2, 2019) is devoted to the topic.

Our focus here has been on one-way (i.e., single-factor) models for ANCOVA and MANCOVA. Of course, it may be of interest to adjust for covariates in experimental contexts involving two or more factors and their interactions. It poses no problem to extend to multifactor studies, and a number of texts provide relevant test statistics and formulas for adjusted cell means in the univariate case (e.g., Neter et al., 1990; Kirk, 1982). In the multivariate case, one would need to alter the MANOVA design matrix, i.e., Z in Eq. (27), to include the appropriate deviation-coded variables; see Timm (2002, p. 246) for details.

Finally, after a rejection of the MANCOVA omnibus null hypothesis, as in the multivariate data demonstration given above, univariate ANCOVA F tests are not the only options for following up to better understand what contributed to the rejection. Instead, for example, one might choose to search for the linear combination of outcome variables that lead to the best separation among treatment groups. This approach, called *discriminant analysis*, is beyond the scope of this chapter but is covered in the multivariate texts referenced herein.

Introduction

When two or more than two attributes are measured, it is often of interest that if there exist any associations or dependence among these attributes. Linear regression is one of the most broadly applied statistical techniques for the modeling of relationships among variables. The term *regression* dates back to [Galton's \(1886\)](#) study on the relationship between the heights of parents and their adult children. [Galton \(1888\)](#) also invented the *index of correlation* and used it to measure the closeness of two variables. Pearson, who was an English mathematician and a notable student of Galton, later expanded Galton's ideas and presented a mathematical treatment of regression ([Pearson, 1896](#)). [Pearson \(1895\)](#) also developed the formula of the still commonly-used Pearson product-moment correlation coefficient (PPMCC). [Slutsky \(1913\)](#) contributed to the development of regression analysis through introducing a goodness of fit test that adopts the assumption of normality. [Fisher \(1922\)](#) synthesized the work of Pearson and the theory of errors of [Gauss's \(1809\)](#), and introduced what is considered the modern regression model. For more information regarding the history of regression analysis, we refer interested readers to sources such as [Stanton \(2001\)](#) and [Aldrich \(2005\)](#).

Since its invention, regression analysis gradually became an active research area. The standard linear regression model, which is the focus of this entry, has been extended to generalized linear models (GLMs; [Nelder and Wedderburn, 1972](#)), hierarchical linear models (HLMs; [Raudenbush and Bryk, 2002](#)), and multivariate regression model. The linear regression model and its extensions have also been applied extensively in a broad spectrum of scientific fields, such as biology and education, for the purposes of making predictions and inferring causal relationships. In addition, the model is considered the foundation of the statistical learning theory ([James et al., 2013](#)), which deals mainly the issue of prediction.

Formulation of linear regression model

Unlike a correlation coefficient such as the PPMCC, which is one single value that quantifies the linear relationship between two variables, a linear regression model describes the relationship between one dependent variable and one or more than one independent variable. The dependent variable, also known as the response or outcome variable, is assumed to be a linear combination of the regression coefficients and independent variable(s), which is also known as the explanatory variable(s) or predictor(s). When only one independent variable is considered, the linear regression model is called *simple linear regression model*. When more than one independent variable is included in the model, it is named *multiple regression model*.

Simple linear regression model

In a simple linear regression model, both the independent variable and the dependent variable are scalars. **Table 1** shows ten simulated observations, each of which consists of measurements of two variables, x and y . Assuming that x is the independent variable and y is the dependent variable, we generate a scatter plot (**Fig. 1**) whose horizontal axis indicates values of x of the observations and the vertical axis shows values of y . The dots in the figure represent the observations (x_i, y_i) , for $i = 1, \dots, 10$. A simple linear regression model that describes the relationship between x and y takes the following form:

$$y_i = \beta_0 + \beta_1 x_i + \varepsilon_i, \quad \text{for } i = 1, \dots, n \quad (1)$$

where n is the total number of observations, and $n = 10$ in the simulated example. The assumed linear relationship between x and y is captured by two unknown but fixed regression coefficients: an intercept β_0 and a slope β_1 . As shown in **Fig. 1**, β_0 indicates the value of y when $x = 0$, and β_1 represents the averaged change in y that is associated with a unit increase in x (e.g., the change in y as x changes from 4 to 5, and from 10 to 11). Once estimated, the regression coefficients can be used to make predictions of y given values of x . ε_i is a disturbance term which represents the part of y that cannot be explained by the independent variable x . In practice, ε_i is often assumed to follow a normal distribution with mean zero and variance σ^2 , $\varepsilon_i \sim \mathcal{N}(0, \sigma^2)$. However, this normality assumption is not required for the estimation of the regression coefficients or the variance of the disturbance term.

Note that in this example, the independent variable x is continuous, but it can be categorical. When the independent variable is categorical, the process of *dummy coding* is usually performed to convert the categorical variable into a series of dummy variables, which can only take the values of 0 and 1. For example, if the variable *region*, which has five categories (*Northeast*, *Southwest*, *West*, *Southeast*, and *Midwest*), is included in a regression model as the independent variable, we can let the category *Northeast* be the

Southwest	1	0	0	0
West	0	1	0	0
Southeast	0	0	1	0
Northeast	0	0	0	1

reference group and create four dummy variables. Each of the four dummy variables indicates if the realization of the variable *region* is *Southwest*, *West*, *Southeast*, or *Midwest* or not, respectively. Table 2 shows the dummy coding process.

The created dummy variables instead of the original variable will be included in the linear regression model. In this case, the intercept coefficient β_0 indicates the average value of y in the reference group (*Northeast*), and the slope coefficients associated with the dummy variables represent the differences in y between the other four groups and the reference group.

In the linear regression analysis, a quantity that is often of interest is the so-called *coefficient of determination*, which is usually denoted by R^2 . R^2 represents the proportion of variation in the dependent variable that can be explained by the independent variable(s), and it ranges from 0 to 1. A R^2 that is close to 1 indicates that the regression model fits the data (i.e., the observations) very well, and it is reliable in terms of making predictions. On the other hand, a R^2 that is close to 0 means that the relationship between the independent and dependent variables is very weak.

In the case of the simple linear regression model, R^2 simply equals the square of the correlation coefficient between the independent and dependent variables (x and y in the simulated example), and can be derived from the slope coefficient β_1 and the data,

$$R^2 = \frac{\beta_1^2 \times \sum_{i=1}^n (x_i - \bar{x})^2}{\sum_{i=1}^n (y_i - \bar{y})^2}, \quad (2)$$

where $\bar{x}$ and $\bar{y}$ represent the means of x_i and y_i ($i = 1, \dots, n$), $\bar{x} = \frac{\sum_{i=1}^n x_i}{n}$ and $\bar{y} = \frac{\sum_{i=1}^n y_i}{n}$, respectively.

Multiple linear regression model

When it comes to the case in which more than one independent variable is assumed to have an impact on the dependent variable, the linear regression process is termed *multiple linear regression*. The dependent variable is expressed as a linear combination of all independent variables. A multiple regression model with p independent variables takes the form:

$$y_i = \beta_0 + \beta_1 x_{i,1} + \beta_2 x_{i,2} + \dots + \beta_p x_{i,p} + \varepsilon_i. \quad (3)$$

In Eq. (3), y_i is the realization of the scalar dependent variable y in the i th observation, and $x_{i,k}$ ($k = 1, \dots, p$) represents the value of the k th independent variables in the i th observation. The multiple regression model contains $p + 1$ parameters: one intercept β_0 and p slope coefficients, each of which corresponds to an independent variable. ε_i is the disturbance term and represents the unexplained part of y_i . ε_i is often assumed to be normally distributed, but this is not necessary for the estimation of the model parameters. A compact form of Eq. (3) is:

$$y_i = \beta_0 + \sum_{k=1}^p \beta_k x_{i,k} + \varepsilon_i. \quad (4)$$

Table 3 shows 10 simulated observations. Each of the ten observations includes values of a dependent variable (y) and two independent variables (x_1 and x_2). If a linear relationship can be assumed between the dependent variable and the two independent variables, a multiple regression model can be written down,

$$y_i = \beta_0 + \beta_1 x_{i,1} + \beta_2 x_{i,2} + \varepsilon_i. \quad (5)$$

The intercept β_0 indicates the value of y when both independent variables are zeros, $x_1 = x_2 = 0$. β_1 is the slope coefficient associated with the first independent variable x_1 , and shows the change in y as x_1 increases by one unit, holding x_2 constant. β_2 is the slope coefficient that corresponds to x_2 , and represents the change in y associated with every one unit increase in x_2 , controlling for x_1 . ε_i is the disturbance term and has a variance of σ^2 .

The linear relationship among x_1 , x_2 , and y can be depicted by a hyperplane in a three-dimension space. The three axes in Fig. 2 indicate values of x_1 , x_2 and y of the simulated observations, respectively, so that each point in the box represents a simulated observation. The hyperplane indicates how y changes as the two independent variables change. To facilitate the understanding of regression coefficients, two more plots are generated. Fig. 3A shows the amount that y would increase if x_1 increases by one unit while fixing x_2 to be 5 and 10, respectively. The two lines in this figure can be viewed as two “slices” of the box shown in Fig. 2. The two parallel lines in Fig. 3B indicate how y changes as x_2 increases while fixing x_1 to be 4 and 8.

The multiple regression model can be expressed in the following matrix form,

Table 3 Simulated data (two predictors).

i	Y	x_1	x_2
1	27	9	5
2	5	0	6
3	23	7	6
4	21	11	5
5	20	6	8
6	26	5	11

8	21	3	11
9	16	3	6
10	37	12	7

Fig. 2 Multiple linear regression The three axes show values of x_1 , x_2 and y of the observations. The linear relationship among them is described by the hyperplane, which is define by β_0 , β_1 and β_2 .

$$y = X\beta + \epsilon, \quad (6)$$

where

$$y = \begin{pmatrix} y_1 \\ \vdots \\ y_n \end{pmatrix}, \quad X = \begin{pmatrix} 1 & x_{1,1} & \dots & x_{1,p} \\ \vdots & \ddots & & \vdots \\ 1 & x_{n,1} & \dots & x_{n,p} \end{pmatrix}, \quad \beta = \begin{pmatrix} \beta_0 \\ \beta_1 \\ \vdots \\ \beta_p \end{pmatrix}, \quad \text{and} \quad \epsilon = \begin{pmatrix} \epsilon_1 \\ \vdots \\ \epsilon_n \end{pmatrix}. \quad (7)$$

In Eq. (6), y is a vector that consists of realizations of the dependent variable in all n observations. X is the so-called *design matrix* and is of size $n \times (p + 1)$. All elements of the first column of X are ones, and correspond to the intercept coefficient β_0 . β is the regression coefficient vector, and consists of one intercept and p slope coefficients, each of which is associated with one independent variable. ϵ is a vector of size n and consists of the disturbance terms. ϵ is often assumed to follow a multivariate normal distribution with mean zeros and a diagonal covariance matrix, whose diagonal elements are all σ^2 and off-diagonal elements are all zeros, $\epsilon \sim \mathcal{N}_n(0, I_n \sigma^2)$. Again, this normality assumption is not required for the estimation of model parameters.

Estimation of linear regression models

The estimation of linear regression models refers to obtaining the model parameters (i.e., the intercept and slope coefficients) that define the “best-fitting” line or hyperplane of the data. The discussion in this section focuses on the ordinary least squares (OLS)

Fig. 3 Illustration of regression coefficients in multiple regression models (A) Change in y as x_1 changes, holding x_2 constant (B) Change in y as x_2 changes, holding x_1 constant.

method, which is one of the most frequently adopted approaches to estimate linear regression models and obtains the “best-fitting” line by minimizing the sum of squared residuals. We demonstrate the OLS approach using a simple regression model. By the end of this section, we introduce briefly the maximum likelihood estimation (MLE) approach.

Ordinary least squares (OLS)

Recall the simple regression model shown in Eq. (1),

$$y_i = \beta_0 + \beta_1 x_i + \varepsilon_i. \quad (8)$$

Let b_0 and b_1 denote some random guesses of the unknown intercept coefficient β_0 and the slope coefficient β_1 . For any set of b_0 and b_1 , a model implied value of y_i can be computed by plugging values of the two guesses into Eq. (1). The differences between the model-implied and observed values of y_i are the so-called *residuals* (illustrated in Fig. 4).

Fig. 4 Illustration of residuals The white dots are the observed data, while the black dots on the line defined by b_0 and b_1 (guesses of the regression coefficients) are the model-implied values. Differences between the observed and model-implied values of y are the residuals.

$$e_i = y_i - (b_0 + b_1 x_i). \quad (9)$$

The least squares estimator of the intercept and slope coefficients, denoted by $\hat{\beta}_0$ and $\hat{\beta}_1$, are the values that minimize the sum of the squared residuals (SSR),

$$SSR = \sum_{i=1}^n e_i^2. \quad (10)$$

The values of $\hat{\beta}_0$ and $\hat{\beta}_1$ can be obtained analytically as,

$$\hat{\beta}_1 = \frac{\sum_{i=1}^n (x_i - \bar{x})(y_i - \bar{y})}{\sum_{i=1}^n (x_i - \bar{x})^2} \quad (11)$$

$$\hat{\beta}_0 = \bar{y} - \hat{\beta}_1 \bar{x}. \quad (12)$$

The $\bar{x}$ and $\bar{y}$ are, as defined in the previous section, the means of x_i and y_i ($i = 1, \dots, n$), respectively. In matrix form, the solution is,

$$\hat{\beta} = (X'X)^{-1}X'y, \quad (13)$$

where $\hat{\beta} = (\hat{\beta}_0, \hat{\beta}_1, \dots, \hat{\beta}_p)$ is a vector that consists of estimates of all regression coefficients, and $(\cdot)^{-1}$ represents the inverse of the matrix in the parentheses.¹

Geometric interpretation of OLS

Let $\hat{y}_i$ ($i = 1, \dots, n$) denote the model-implied values of the dependent variable associated with the OLS estimator $\hat{\beta}_0$ and $\hat{\beta}_1$, and $\hat{e}_i$ be the corresponding residual,

$$\hat{y}_i = \hat{\beta}_0 + \hat{\beta}_1 x_i \quad (14)$$

$$\hat{e}_i = y_i - \hat{y}_i. \quad (15)$$

In other words, $\hat{y}_i$ is a dot on the “best-fitting” line of the data. All model predicted values can be stacked in a vector, denoted by $\hat{\mathbf{y}}$, and

$$\hat{\mathbf{y}} = X\hat{\beta}. \quad (16)$$

¹Note that this assumes that X is full column rank so that $X'X$ is invertible. When X is not full rank, alternative solutions such as generalized inverses (Searle, 1971) can be applied.

Fig. 5 Geometric interpretation of ordinary least squares estimation.

Similarly, let $\hat{e}$ denote the vector of $\hat{e}_i$ for $i = 1, \dots, n$.

The ordinary least squares estimation has a geometric interpretation. As shown in Fig. 5, the predicted value vector $\hat{y}$ is the projection of the observed values y onto the space spanned by columns of the design matrix X (a vector of ones and a vector of all x_i in the simple linear regression case). The vector y is the sum of $\hat{y}$ and $\hat{e}$, which is orthogonal to the space spanned by the columns of X . Since $\hat{e}$ is orthogonal to the space, its length is the smallest among residual vectors associated with all possible values of b_0 and b_1 .

Standard errors, confidence intervals and hypotheses testing of β

Once $\hat{\beta}$ are obtained, we can quantify the uncertainty around these point estimates of regression coefficients via the calculation of the associated standard errors. The OLS approach does not require that the disturbance term ε_i follows a normal distribution to produce unbiased point estimates of the regression coefficients and the variance of ε_i . The covariance matrix of $\hat{\beta}$, represented by the letter Σ , can be calculated as:

$$\Sigma = (X'X)^{-1}\hat{\sigma}^2. \quad (17)$$

In Eq. (17), $\hat{\sigma}^2$ denotes an unbiased estimator of the unknown variance of the disturbance terms σ^2 . $\hat{\sigma}^2$ is computed as:

$$\hat{\sigma}^2 = \frac{\sum_{i=1}^n (y_i - \mathbf{x}_i' \hat{\beta})^2}{n - p - 1}, \quad (18)$$

in which $\mathbf{x}_i = (1, x_{i,1}, \dots, x_{i,p})$ consists of a one and values of p independent variables in the i th observation. The standard errors of $\hat{\beta}$ can be obtained by taking the square root of the diagonal elements of Σ .

If the normality assumption of ε_i holds, we can construct a confidence interval of a specific regression coefficient for any significance levels. For example, a 95% confidence interval of β_k (the k th element of β) is:

$$\left(\hat{\beta}_k - t^{0.975} \sqrt{\Sigma_{k,k}}, \quad \hat{\beta}_k + t^{0.975} \sqrt{\Sigma_{k,k}} \right), \quad (19)$$

where $t^{0.975}$ is the 97.5% percentile of a t distribution with $n - p - 1$ degrees of freedom. $\Sigma_{k,k}$ represents the k th diagonal element of the covariance matrix Σ . We are 95% confident that the true value of β_k lies within this confidence interval.

We can also conduct hypothesis testing of the regression coefficients if ε_i is assumed to follow a normal distribution. For example, to examine if β_k equals a constant c , we can form the below test statistic:

$$t_k = \frac{\hat{\beta}_k - c}{\sqrt{\Sigma_{k,k}}}. \quad (20)$$

Under the null hypothesis that $\beta_k = c$, this test statistic follows a t -distribution with $n - p - 1$ degrees of freedom. A t_k that is too large or too small would lead to the rejection of the null hypothesis and the conclusion that β_k is unlikely to be equal to c .

Maximum likelihood estimation (MLE)

In addition to the OLS approach, another widely-used approach to estimate linear regression models is the maximum likelihood estimation (MLE). Recall that the disturbance term ε_i is independent of the design matrix X and also independent across observations. If the normality assumption of ε_i holds, conditional on x_i , y_i would also follow a normal distribution with the mean $\beta_0 + \beta_1 x_i$ and variance σ^2 , $y_i \sim \mathcal{N}(\beta_0 + \beta_1 x_i, \sigma^2)$. The conditional probability density of y_i given x_i and the true model parameters is,

$$p(y_i | x_i; \beta_0, \beta_1, \sigma^2) = \frac{1}{\sigma \sqrt{2\pi}} e^{-\frac{1}{2} \left[\frac{y_i - (\beta_0 + \beta_1 x_i)}{\sigma} \right]^2}. \quad (21)$$

The conditional probability density of the data can be obtained by multiplying together the probability densities of all n observations,

$$\prod_{i=1}^n p(y_i|x_i; \beta_0, \beta_1, \sigma^2) = \prod_{i=1}^n \frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{1}{2} \left[\frac{y_i - (\beta_0 + \beta_1 x_i)}{\sigma} \right]^2}. \quad (22)$$

Let $L(b_0, b_1, s^2)$ denote the likelihood associated with some random guesses of the model parameters β_0 , β_1 , and σ^2 . With the MLE approach, we would like to find the values of b_0 , b_1 , and s^2 that maximizes $L(b_0, b_1, s^2)$. For convenience, we usually work with the log-likelihood, which is obtained by simply taking the logarithm of the likelihood. Parameter values that maximize the log-likelihood also maximize the likelihood,

$$l(b_0, b_1, s^2) = \log L(b_0, b_1, s^2) = \log \prod_{i=1}^n p(y_i|x_i; b_0, b_1, \sigma^2) = -\frac{n}{2} \log 2\pi - n \log s - \frac{1}{2s^2} \sum_{i=1}^n [y_i - (b_0 + b_1 x_i)]^2. \quad (23)$$

The MLE approach yields the same point estimates of regression coefficients as the OLS approach.

Assumptions of linear regression model

As alluded in the previous sections, the linear regression model along with the associated estimation approaches (such as the OLS) require certain assumptions about the independent variables, the disturbance term and their relationships to be satisfied. In this section, we briefly review a few major assumptions made by the linear regression model.

Linearity

The linear regression model assumes that the expectation of the scalar dependent variable is a linear combination of the independent variables and the regression coefficients. Note that the assumption of linearity is about the regression coefficients in the sense that the independent variables can be transformed arbitrarily. Thus, some basic expansions of the independent variables, such as $x_2 = x_1^2$, can also be included in the linear regression models. In other words, the following model:

$$y_i = \beta_0 + \beta_1 x_1 + \beta_2 x_2^2 + \varepsilon_i \quad (24)$$

is recognized as a linear regression model.

No multicollinearity among independent variables

A major assumption made by the linear regression model on the independent variables is that there exists no multicollinearity among them. Multicollinearity refers to the situation where values of a specific independent variable can be obtained by linearly combining other independent variables, such as $x_2 = 2x_1$. If there exists strong linear relationships among independent variables, columns of the design matrix $\mathbf{X}$ would not be linearly independent. In other words, $\mathbf{X}$ would not be full rank. This will lead to the consequence that estimates of the regression coefficients are not uniquely defined with the OLS approach. Multicollinearity is also used to describe situations where a combination of independent variables is highly correlated with another independent variable. Note that the independent variables remain linearly independent but the regression coefficients will be poorly estimated.

The variance inflation factor (VIF) quantifies the severity of multicollinearity and can be used to examine the assumption in the linear regression model. A large VIF indicates that there exists a strong correlation between the independent variables. If there is complete collinearity, then the VIF will be infinity.

Distribution of disturbance term

Assumptions are also made about the distribution of the disturbance term and the relationship between the disturbance term and the independent variable(s). For example, with the OLS approach, the disturbance term has to follow a normal distribution to create confidence intervals and conduct hypothesis testing of the regression coefficients.

In addition, the disturbance term is assumed to be independent with the independent variable(s) and also with each other. This independence assumption can be easily violated in time series data where an individual is measured at multiple time points. Approaches such as the generalized least squares (GLS) can be used to handle the correlated disturbances.

Homoscedasticity

The assumption of homoscedasticity, also known as the homogeneity of variance assumption, states that the variances of the disturbance terms are the same across observations. Stated in another way, all elements on the diagonal of the covariance matrix of $\boldsymbol{\varepsilon}$ have the same value.

The homoscedasticity assumption can be examined by plotting the residuals against the dependent variable. If this assumption is violated, the weighted least squares (WLS) approach can be applied to deal with the problem.

Extensions of linear regression model

In a standard linear regression model, the dependent variable is a continuous variable and would follow a normal distribution if the disturbance term is normally distributed. In this section, we introduce three extensions of the standard linear regression model: the generalized linear model (GLM), the hierarchical linear model (HLM), and the multivariate linear model. The GLM allows the dependent variable to follow an arbitrary distribution. The HLM accommodates data with more than one level. The multivariate linear model allows the modeling of the relationship among independent variables and multiple dependent variables.

Generalized linear model

The generalized linear model (GLM; [Nelder and Wedderburn, 1972](#)) extends the linear regression model and can be viewed as a general framework. With a GLM, data whose dependent variable follows distributions other than the normal distribution can be modeled appropriately. A GLM consists of three elements: a dependent variable that can follow an arbitrary distribution, a linear predictor, which is a linear combination of the independent variables and regression coefficients, and a link function,

$$\mathbb{E}[y_i | \mathbf{x}_i] = \mu_i \quad (25)$$

$$g(\mu_i) = \mathbf{x}_i' \boldsymbol{\beta}. \quad (26)$$

In [Eq. \(25\)](#), μ_i is the conditional expectation of the dependent variable y_i given the independent variables $\mathbf{x}_i$, $\mathbf{x}_i' \boldsymbol{\beta}$ is the linear predictor, and $g(\cdot)$ the so-called *link function*, which is a known function that maps the linear predictor to the desired distribution. For example, when the dependent variable is assumed to follow a Bernoulli distribution (i.e., y_i can only take the values of 0 and 1), the logit link function can be applied so that the linear predictor (which ranges from $-\infty$ to ∞) is mapped to the 0–1 range,

$$\mu_i = \frac{1}{1 + \exp(-\mathbf{x}_i' \boldsymbol{\beta})}. \quad (27)$$

Another example is that if the dependent variable follows a Poisson distribution and takes the values of nonnegative integers, a log link function can be applied,

$$\log(\mu_i) = \mathbf{x}_i' \boldsymbol{\beta}. \quad (28)$$

The standard linear regression model presented in previous sections can be viewed as a special case of the generalized linear model. The link function in a standard linear regression model is the identity link function,

$$\mu_i = \mathbf{x}_i' \boldsymbol{\beta}. \quad (29)$$

Hierarchical linear model

The hierarchical linear model (HLM; [Raudenbush and Bryk, 2002](#)), which is also known as the multilevel model ([Goldstein, 2011](#)), is another extension of the standard linear regression model. The HLM can be applied to data with more than one level, which are prevalent in social and behavioral sciences. A canonical example in the field of education of two-level data is that students are nested within classrooms. A two-level HLM can be formulated as follows: at level 1 (the student level), the outcome of the i th student in classroom j is expressed as the linear combination,

$$y_{ij} = \beta_{0j} + \beta_{1j}x_{ij} + \varepsilon_{ij} \quad (30)$$

in which β_{0j} and β_{1j} are the group-specific intercept and slope coefficients, x_{ij} is a level-1 independent variable (i.e., a student-related variable), and ε_{ij} is the associated disturbance term, $\varepsilon_{ij} \sim \mathcal{N}(0, \sigma^2)$. At level 2 (the classroom level), the group-specific intercept and slope coefficients are modeled,

$$\beta_{0j} = \gamma_{00} + \gamma_{01}w_j + u_{0j} \quad (31)$$

$$\beta_{1j} = \gamma_{10} + u_{1j}, \quad (32)$$

where γ_{00} and γ_{10} are the average intercept and slope across groups, w_j is a level-2 independent variable (i.e., a classroom-related variable), γ_{01} is the associated regression coefficients and represents how the group-specific intercept changes as w_j changes. u_{0j} and u_{1j} are deviations of group-specific coefficients to the averages, and are assumed to follow a bivariate normal distribution,

$$\begin{pmatrix} u_{0j} \\ u_{1j} \end{pmatrix} \sim N \left[\begin{pmatrix} 0 \\ 0 \end{pmatrix}, \begin{pmatrix} \sigma_{00} & \sigma_{01} \\ \sigma_{10} & \sigma_{11} \end{pmatrix} \right].$$

Note that the off-diagonal elements σ_{01} and σ_{10} can be nonzero, indicating the deviations of the intercept and slope can be correlated.

In addition to the example discussed above, more complex models for multiple level-1 and level-2 independent variables and more complex models for level-1 coefficients are possible and widely used, such as the cross-classified multilevel model (Goldstein, 1994).

Multivariate linear model

If there are more than one dependent variable in the observations, and a linear relationship is assumed between the independent and dependent variables, the multivariate regression model can be used to model the relationship. The multivariate regression model takes the following form:

$$\mathbf{y}_i = \mathbf{B}\mathbf{x}_i + \boldsymbol{\varepsilon}_i. \quad (33)$$

In Eq. (33), $\mathbf{y}_i$ is a vector of size m and includes values of m dependent variables in the observation i . $\mathbf{x}_i$ is a vector of independent variables and is of size p , and $\mathbf{B}$ is the corresponding regression coefficient matrix, the size of which is $m \times p$. $\boldsymbol{\varepsilon}_i$ is a vector of the disturbance terms and is often assumed to follow a multivariate normal distribution with mean zeros and covariance matrix Ψ , $\boldsymbol{\varepsilon}_i \sim \mathcal{N}_m(0, \Psi)$. The disturbance terms in the same observation may have different variances and can be correlated. The generalized least squares (GLS) approach can be used to obtain estimates of the model parameters in the multivariate regression model.

Conclusion

In this article, we present the formulation of the standard linear regression model, which is one of the most broadly applied statistical techniques to investigate the relationship between one dependent variable and one or more than one independent variable. We review how to obtain estimates of the regression coefficients and the variance of the disturbance term via the approaches of ordinary least squares (OLS) and maximum likelihood estimation (MLE). We also discuss a few assumptions that underlie the linear regression model, including assumptions about independent variables, distribution of the disturbance term, and the relationship among variables. In addition, we show three major extensions of the linear regression model, the generalized linear model (GLM), hierarchical linear model (HLM), and multivariate regression model.

Last but not least, although not discussed in this entry, we would like to highlight that linear regression model also plays a fundamental role in the field of statistical learning, which is also known as machine learning. We conclude that the regression analysis will remain an active research area, and the linear regression model and its extensions will be applied successfully in various scientific fields.

Introduction

An overview of the nonlinear regression models

Nonlinear regression models have been widely used in various fields including statistics, chemistry, physics, psychology, health science, and biology. Some of them have a linear relationship in the parameters (i.e., linear in the θ). For example, a polynomial regression fits a curved relationship between the response variable and predictors using higher-ordered values of the predictors, but it is linear in terms of the parameters. Statistical inference can be derived from nonlinear regression models (Eq. 1). The main advantages of nonlinear regression models include interpretability, parsimony, and prediction (Bates and Watts, 1988). In general, nonlinear models are capable of accommodating various mean functions, so nonlinear models are appropriate for applications with parsimonious parameters and easily interpretable due to the fact that the parameters can be associated with meaningful factors.

Assume that there are n observations of responses $y_1, \dots, y_n$ and predictors $\mathbf{x}_{ik}$ associated with y_i on $k = 1, \dots, p$ independent variables. In nonlinear regression, the y 's and $\mathbf{x}$'s satisfy the nonlinear regression model

$$y_i = f(\mathbf{x}_i, \theta) + \varepsilon_i, \quad i = 1, \dots, n, \quad (1)$$

where f is a function that is nonlinear in the p elements of parameter θ with the unknown true value θ^* , and the ε_i 's are independent and identically distributed (i.i.d) random errors with mean zero and constant variance σ^2 . The conditional mean response $E(y_i | \mathbf{x}_i) = f(\mathbf{x}_i, \theta)$, so we will refer to f as the mean function. For example, the Beverton-Holt model (Beverton and Holt, 2012) which is similar to the Michaelis-Menten model (Sheiner and Beal, 1980) and used for modeling discrete-time population gives the expected population $y = n_{t+1}$ as a function of the previous population $\mathbf{x} = n_t$ as

$$n_{t+1} = f(\mathbf{x}, (\alpha, \beta)) = \frac{\alpha \mathbf{x}}{1 + \mathbf{x}/\beta},$$

where $\theta = (\alpha, \beta)$ and the parameter α is the slope at 0 and β is the concentration between 0 and the upper limit $\alpha\beta$. It is a nonlinear regression since the two variables are related in a nonlinear (curved) relationship.

Estimation methods

In order to estimate the parameters in a nonlinear regression model, we minimize the sum of squared residuals, which measures how far the y observations vary from the nonlinear function $f(\mathbf{x}_i, \theta)$ used to predict y . Such estimators are called the least squares estimators $\hat{\theta}$ of θ , that is,

$$S(\theta) = \sum_{i=1}^n (y_i - f(\mathbf{x}_i, \theta))^2$$

is used to find

$$\hat{\boldsymbol{\theta}} = \underset{\boldsymbol{\theta}}{\operatorname{argmin}} S(\boldsymbol{\theta}).$$

For example, to estimate α and β in the Beverton-Holt model, we minimize $S(\alpha, \beta) = \sum \left(y_i - \frac{\alpha x_i}{1 + x_i/\beta} \right)^2$. We first derive the gradients g_α, g_β and Hessian matrix with elements H_{ij} , $i, j \in \{\alpha, \beta\}$ as follows:

$$\begin{aligned} g_\alpha &= \frac{\partial S(\boldsymbol{\theta})}{\partial \alpha} = -2 \sum \mathbf{x}_i \left(y_i - \frac{\alpha x_i}{1 + x_i/\beta} \right), \\ g_\beta &= \frac{\partial S(\boldsymbol{\theta})}{\partial \beta} = -2 \sum \left(y_i - \frac{\alpha x_i}{1 + x_i/\beta} \right) \frac{\alpha x_i^2}{\beta^2 (1 + x_i/\beta)^2}, \\ H_{\alpha, \alpha} &= \frac{\partial g_\alpha}{\partial \alpha} = 2 \sum \frac{x_i^2}{1 + x_i/\beta}, \\ H_{\alpha, \beta} &= \frac{\partial g_\alpha}{\partial \beta} = 2 \sum \frac{\alpha x_i^3}{\beta^2 (1 + x_i/\beta)^2}, \\ H_{\beta, \alpha} &= -2 \sum \frac{x_i^2 y_i}{\beta^2 (1 + x_i/\beta)^2} - \frac{x_i^3}{\beta^2 (1 + x_i/\beta)^3}, \text{ and} \\ H_{\beta, \beta} &= -2 \sum \frac{-2\alpha x_i^2 y_i}{(\beta + x_i)^3} + \frac{2\alpha^2 x_i^3}{\beta^3 (1 + x_i/\beta)^3} - \frac{3\alpha^2 x_i^4}{\beta^4 (1 + x_i/\beta)^4}. \end{aligned}$$

Then we can use the Gauss-Newton or Newton-Raphson methods to iteratively estimate α and β introduced in the **Gauss-Newton method for least squares estimation** and **Newton-Raphson method** sections, respectively. The Gauss-Newton method is essentially the Newton-Raphson method with the modification that the Gauss-Newton method uses the approximation $2J^T J$, where J is the Jacobian matrix, for the Hessian matrix. Note that for a scalar nonlinear function, its Jacobian matrix is the same as the gradient.

Gauss-Newton method for nonlinear least-squares problems

When f is twice differentiable with respect to $\boldsymbol{\theta}$, we have the gradient and Hessian which can be written as:

$$\begin{aligned} g_j &= \frac{\partial S(\boldsymbol{\theta})}{\partial \theta_j} = -2 \sum_{i=1}^n (y_i - f_i) \frac{\partial f_i}{\partial \theta_j}, \\ H_{jk} &= \frac{\partial^2 S(\boldsymbol{\theta})}{\partial \theta_j \partial \theta_k} = -2 \sum_{i=1}^n \left((y_i - f_i) \frac{\partial^2 f_i}{\partial \theta_j \partial \theta_k} - \frac{\partial f_i}{\partial \theta_j} \frac{\partial f_i}{\partial \theta_k} \right) \end{aligned}$$

where $f_i = f(\mathbf{x}_i, \boldsymbol{\theta})$.

Further, we solve for the least-squares solution $\hat{\boldsymbol{\theta}}$ in the following system of equations

$$\left. \frac{\partial S(\boldsymbol{\theta})}{\partial \theta_j} \right|_{\boldsymbol{\theta}=\hat{\boldsymbol{\theta}}} = 0; \quad j = 1, \dots, p, \quad (2)$$

which are called the normal equations with

$$\sum_{i=1}^n (y_i - f_i) \frac{\partial f(\boldsymbol{\theta})}{\partial \theta_j} \Big|_{\boldsymbol{\theta}=\hat{\boldsymbol{\theta}}} = 0.$$

Its matrix form is

$$\mathbf{J}(\hat{\boldsymbol{\theta}})^T \mathbf{r} = 0$$

with (i, j) -th element $J_{ij}(\hat{\boldsymbol{\theta}}) = \frac{\partial f_i}{\partial \theta_j}$ and $\mathbf{r} = \mathbf{y} - f(\hat{\boldsymbol{\theta}})$ with the i -th element $r_i = y_i - f_i$. The matrix $\mathbf{J}(\hat{\boldsymbol{\theta}})$ of size $n \times p$ is called the Jacobian matrix. Define the $p \times p$ matrices $G_1, \dots, G_n$ so that the (j, k) -th element of G_i is $\frac{\partial^2 f_i}{\partial \theta_j \partial \theta_k}$, and then the gradient and Hessian are given by

$$\mathbf{g} = -2\mathbf{J}^T \mathbf{r}, \quad \mathbf{H} = 2\mathbf{J}^T \mathbf{J} - 2 \sum_{i=1}^n r_i G_i. \quad (3)$$

In a linear regression model, the Jacobian is simply the data design matrix $\mathbf{X}$ and does not depend on the parameter values $\boldsymbol{\theta}$.

The normal equations do not have an analytic solution for $\hat{\theta}$ in most cases, so that numerical iterative procedures are needed. The Gauss-Newton method estimates the parameters in nonlinear regression using the first-order Taylor's expansion

$$f(\mathbf{x}, \theta) \approx f(\mathbf{x}, \theta^*) + \nabla f(\mathbf{x}, \theta)^T (\theta - \theta^*)$$

to approximate a nonlinear regression function (Nadaraya, 1964; Ruppert and Wand, 1994) considering a small neighborhood of θ^* . The linear approximation of $f(\mathbf{x}, \theta)$ in the neighborhood of θ^* results in an approximate residual sum of squares

$$S(\theta) \approx \sum_{i=1}^n \left(y_i - f(\mathbf{x}_i, \theta^*) - \sum_j^p J_{ij}^T (\theta_j - \theta_j^*) \right)^2,$$

and

$$S(\theta) - S(\theta^*) \approx (\hat{\theta} - \theta^*)^T \mathbf{J}^T \mathbf{J} (\hat{\theta} - \theta^*). \quad (4)$$

The corresponding normal equations at the t -th iteration are given by

$$\mathbf{J}(\theta^{(t)})^T \mathbf{J}(\theta^{(t)}) (\theta - \theta^{(t)}) = \mathbf{J}(\theta^{(t)})^T (y - f(\theta^{(t)})).$$

The updating increment

$$\delta^{(t)} = \left(\mathbf{J}(\theta^{(t)})^T \mathbf{J}(\theta^{(t)}) \right)^{-1} \mathbf{J}(\theta^{(t)})^T (y - f(\theta^{(t)}))$$

in the t -th iteration, and then $\theta^{(t+1)} = \theta^{(t)} + \lambda_t \delta^{(t)}$ where λ_t is the step size. The update direction $\delta^{(t)}$ is derived from the tangent plane approximation to the solution locus.

The estimate of the asymptotic covariance of the least squares estimate is given by

$$\text{cov}(\hat{\theta}) = \sigma^2 (\mathbf{J}^T \mathbf{J})^{-1}.$$

The statistical inference about θ is based on the property that $\hat{\theta}$ follows $N(\theta, \sigma^2 (\mathbf{J}^T \mathbf{J})^{-1})$ asymptotically. σ^2 is estimated by $s^2 = S(\hat{\theta})/(n-p)$, where p is the number of parameters and $\mathbf{J}$ is estimated by $\mathbf{J}(\hat{\theta})$.

Maximum likelihood estimation

Considering a normal distributed error term

$$y_i - f(\mathbf{x}_i, \theta) \stackrel{i.i.d.}{\sim} N(0, \sigma^2),$$

the log-likelihood function of θ and σ^2 is

$$l(\theta, \sigma^2) = -\frac{S(\theta)}{2\sigma^2} - \frac{n}{2} \log(2\pi\sigma^2).$$

Maximum likelihood estimation (MLE) is a method of estimating the parameters by maximizing $l(\theta, \sigma^2)$ with respect to θ and σ^2 for which we need the following derivatives

$$\frac{\partial l}{\partial \sigma^2} = \frac{1}{2\sigma^4} S(\theta) - \frac{n}{2\sigma^2}, \quad (5)$$

$$\frac{\partial l}{\partial \theta} = -\frac{1}{2\sigma^2} \frac{\partial S(\theta)}{\partial \theta}. \quad (6)$$

Setting Eqs. (5) and (6) equal to 0, we have $\hat{\sigma}_{\text{MLE}}^2 = \frac{S(\hat{\theta})}{n}$ and the normal Eq. (2). As a result, $\hat{\theta}_{\text{MLE}} = \hat{\theta}$. In summary, when the noise follows a normal distribution, the Gauss-Newton iterations to minimize the least squares $S(\theta)$ are exactly the same as the Newton-Raphson iterations to maximize the log-likelihood function with respect to θ , and hence the maximum likelihood estimator is equivalent to the least squares estimator (Bates and Watts, 1988).

Asymptotic statistical inference

Let us consider the nonlinear regression model (Eq. 1) where the $\varepsilon_i \stackrel{i.i.d.}{\sim} N(0, \sigma^2)$. We note that as $n \rightarrow \infty$, the least squares estimate $\hat{\theta}$ is asymptotically $N(\theta^*, \sigma^2 (\mathbf{J}^T \mathbf{J})^{-1})$, where θ^* is the true value of θ , and the matrix $\mathbf{J} = [\partial f(\mathbf{x}_i; \theta) / \partial \theta_j]_{\theta^*}$ plays the same role as X in the linear regression (Saber and Wild, 1989). In particular, by analogy with the linear confidence region

$$\left\{ \theta \mid (\theta - \hat{\theta})^T \hat{J} (\theta - \hat{\theta}) \leq p s^2 F_{p, n-p}^\alpha \right\}, \quad (7)$$

is an approximate $100(1 - \alpha)\%$ confidence region for θ . Here $s^2 = S(\hat{\theta})/(n - p)$, $\hat{J} = J(\hat{\theta})$, and $F_{p, n-p}^\alpha$ is the upper critical value of the $F_{p, n-p}$ distribution. As the linear approximation is valid asymptotically, (Eq. 7) will have the correct confidence level of $100(1 - \alpha)\%$ asymptotically. As α varies, the regions (Eq. 7) are ellipsoid contours of the approximate multivariate normal density function of $\hat{\theta}$ (with J replaced by $\hat{J}$). Since $S(\theta)$ measures how close the observations are to the fitted equation for any θ , it would seem appropriate to also base confidence regions for θ on the contours of $S(\theta)$. Such a region could take the form

$$\left\{ \theta \mid S(\theta) \leq c S(\hat{\theta}) \right\}$$

for some c , $c > 1$. Regions of this type are often called the exact confidence regions, as they are not based on any approximations. However, the confidence levels, or coverage probabilities, of such regions are generally unknown, though approximate levels can be obtained from asymptotic theory.

For large enough n , the consistent estimator $\hat{\theta}$ will be sufficiently close to θ^* for the approximation (Eq. 4) to hold with $F_{p, n-p}^\alpha$ in Eq. (7). Therefore, substituting

$$S(\theta^*) - S(\theta) \approx (\hat{\theta} - \theta^*)^T \hat{J}^T \hat{J} (\hat{\theta} - \theta^*) \quad (8)$$

from Eq. (4), we obtain the confidence region

$$\left\{ \theta \mid S(\theta) \leq S(\hat{\theta}) \left(1 + \frac{p}{n - p} F_{p, n-p}^\alpha \right) \right\} \quad (9)$$

that has the required asymptotic confidence level of $100(1 - \alpha)\%$. The regions Eqs. (7) and (9) are asymptotically the same, and they are identical for linear models. However, for finite n , these regions may be very different, and it indicates inadequacy of the linear approximation (Eq. 4). Under the assumption of normal errors we see that the above clash between the two confidence regions embodies a wider principle. We have a choice between confidence regions based on the asymptotic normality of the maximum likelihood estimator $\hat{\theta}$, which is also the least squares estimator, and those based on the contours of the likelihood function via the likelihood ratio test.

Parameterization and curvature

There are some nonlinear models which are intrinsically linear because they can be made linear in the parameters by a simple transformation. For example, the reciprocal of the Michaelis-Menten regression mean function

$$f(x, \mathbf{b}) = \frac{b_1 x}{b_2 + x} \quad (10)$$

results in the model

$$\frac{1}{y} = \frac{1}{b_1} + \frac{b_2}{b_1} \frac{1}{x} + \varepsilon = \beta_1 + \beta_2 \frac{1}{x} + \varepsilon,$$

which is linear in the transformed parameters β_1 and β_2 . In such cases, transforming a model to its linear form often provides better inference procedures and confidence intervals. However, parameterization may affect the asymptotic variance and convergence of the estimation algorithm (Bates and Watts, 1988; Huang et al., 2010). The re-parameterization is an important issue. Although the shape of the solution locus is fixed, the performance of the Gauss-Newton estimator varies with respect to different parameterizations. This depends on the nonlinearity in the model. There are two kinds of nonlinearity—*intrinsic nonlinearity* and *parameter-effects nonlinearity* (Hamilton and Watts, 1985; Bates and Watts, 1988). The *intrinsic nonlinearity* is associated with the modeling and is invariant under parameterization. The *parameter-effects nonlinearity*, however, can be lessened through a proper parameterization. If either component of the nonlinearity is large, the least squares estimate may not converge. Furthermore, the estimated covariance for $\hat{\mathbf{b}}$ given by $\hat{V}(\hat{\mathbf{b}}) = \hat{\sigma}^2 (J(\hat{\mathbf{b}})^T J(\hat{\mathbf{b}}))^{-1}$, would change greatly in each step of the iteration, and the statistical inference based on the asymptotic normality becomes unreliable. In other words, the least squares estimator in nonlinear regression depends on the curvedness of the underlying model as well as the parameterization adopted.

The quality of the linear approximation can be summarized by *intrinsic curvature* $\kappa_d^N = \|d^T C_N d\|$ and *parameter-effects curvature* $\kappa_d^T = \|d^T C_T d\|$ (Bates and Watts, 1988), where d has unit length, C_N is the normal direction curvature matrix, and C_T is the tangent direction curvature matrix. For details on curvatures, please read the Appendix in Huang et al. (2010).

The two curvatures correspond to two assumptions of linear approximation of a nonlinear mean function. First, the planar assumption ensures that the nonlinear mean function is approximated by its tangent plane at a given point. Second, the uniform coordinate assumption means that an equi-spaced, straight and parallel linear coordinate system is placed on the approximation tangent plane. *Intrinsic curvature* is related to the planar assumption, and it depends on the dataset considered and the mean function but not on the parameterization used in the mean function. *Parameter-effects curvature* is related to the uniform coordinate

Fig. 1 The profile plots of the simulation data analysis. The 95% confidence region of b_1 and b_2 using the Wald statistic (dashed), the likelihood ratio (blue) and Skovgaard's approximation (red) with simulated data from the Michaelis-Menten model. The left panel is with sample size $n = 50$, and the right panel is with sample size $n = 100$.

assumption, and it depends on all aspects of the model, including the parameterization. Large values of these two curvature measures indicate a poor linear approximation. The function `rms.curv()` in the R package MASS can be used to calculate the two measures for a given `nls()` model fit (Venables and Ripley, 2002). The intrinsic curvature is generally relatively negligible compared with the parameter-effects curvature (Bates and Watts, 1988), and in such cases the profile likelihood approach is useful.

The Wald, likelihood ratio (LR) and score tests are asymptotically equivalent. They all have the same sampling distribution which is a chi-square distribution with the same degrees of freedom. However, the Wald test statistics $(\hat{\mathbf{b}} - \mathbf{b}_0)^T [\hat{\mathbf{V}}(\hat{\mathbf{b}})]^{-1} (\hat{\mathbf{b}} - \mathbf{b}_0)$, which results in an ellipsoidal confidence region, uses $\hat{\mathbf{b}}$ and depends on curvature of the likelihood at $\hat{\mathbf{b}}$. The score test depends on the slope and curvature at $\hat{\mathbf{b}}_0$, while the LR test uses information from both $\hat{\mathbf{b}}$ and $\hat{\mathbf{b}}_0$. The differences among them vanish in large samples if the null hypothesis is true. If the null hypothesis is false, they may take very different values. The Wald procedures are influenced by both intrinsic curvature and parameter-effects curvature. A model with a lower parameter-effects curvature is preferable.

The curvature can affect the quality of statistical inferences based on the asymptotic normality. When the mapped parameter curves onto the tangent plane are not uniform grid lines, the resulting confidence region may not be reliable. We use the Michaelis-Menten model (Eq. 10) as an example by simulating data with $\varepsilon_i \stackrel{i.i.d.}{\sim} N(0, 1^2)$, $b_1 = 6$, $b_2 = 5$, and $\mathbf{x}$ generated from the uniform distribution (1, 100). We demonstrate how confidence regions of b_1 and b_2 are affected by curvatures with two different sample sizes $n_1 = 50$ and $n_2 = 100$ displayed in Fig. 1 using the contour method of the nlreg package (Brazzale, 2005). The dashed, blue and red lines represent the confidence regions of (b_1, b_2) obtained with the Wald test, the likelihood ratio test, and Skovgaard's approximation, respectively (Skovgaard, 1996). The confidence regions of the latter two methods are closer to the exact one than the Wald (Bates and Watts, 1988; Skovgaard, 1996). When the sample size is small, the shapes and coverage between the Wald confidence region and the two others are very different. As the sample size grows, they become less different.

Newton-Raphson method

The Newton-Raphson method (also called Newton's method) which has been widely used for estimating the parameters of nonlinear regression models due to its advantage of fast convergence using the second order Taylor's expansion to approximate the nonlinear function $l(\boldsymbol{\theta})$ as a quadratic polynomial as follows:

$$l(\boldsymbol{\theta}) \approx l(\boldsymbol{\theta}^{(t)}) + (\boldsymbol{\theta} - \boldsymbol{\theta}^{(t)})^T \nabla l(\boldsymbol{\theta}^{(t)}) + \frac{1}{2} (\boldsymbol{\theta} - \boldsymbol{\theta}^{(t)})^T \nabla^2 l(\boldsymbol{\theta}^{(t)}) (\boldsymbol{\theta} - \boldsymbol{\theta}^{(t)}), \quad (11)$$

where $\boldsymbol{\theta}^{(t)}$ is in a neighborhood of the true $\boldsymbol{\theta}$, ∇ is the first derivative and ∇^2 is the second derivative with respect to $\boldsymbol{\theta}$. The Newton-Raphson method can be computationally challenging and heavily dependent on good starting values (Gill et al., 1986). To maximize the quadratic approximation, we set the first derivative of the approximate quadratic function (Eq. 11) equal to 0 at a new point $\boldsymbol{\theta}^{(t+1)}$.

$$\begin{aligned} \nabla l(\boldsymbol{\theta}^{(t)}) + [\nabla^2 l(\boldsymbol{\theta}^{(t)})] (\boldsymbol{\theta}^{(t+1)} - \boldsymbol{\theta}^{(t)}) &= \mathbf{0}_p, \\ \boldsymbol{\theta}^{(t+1)} &= \boldsymbol{\theta}^{(t)} - [\nabla^2 l(\boldsymbol{\theta}^{(t)})]^{-1} \nabla l(\boldsymbol{\theta}^{(t)}) \\ &= \boldsymbol{\theta}^{(t)} + [-\nabla^2 f(\boldsymbol{\theta}^{(t)})]^{-1} \nabla f(\boldsymbol{\theta}^{(t)}) \end{aligned}$$

which approximates $\boldsymbol{\theta}$ in each iteration t . The value $\boldsymbol{\theta}^{(t+1)}$ should be a better guess than the initial point $\boldsymbol{\theta}^{(t)}$ is.

Here, we focus on deriving the Newton-Raphson method for the exponential family (Nelder and Wedderburn, 1972) including the Gaussian (normal) distributions for continuous variables, binomial distributions for binary response variables, Poisson

distributions for count variables, and the gamma and inverse-Gaussian families of distributions for modeling positive continuous data, where the conditional variance of y_i increases with its expectation. The log-likelihood for n independent observations from an exponential family is given by

$$L_n(\boldsymbol{\theta}, \phi; \boldsymbol{y}) = \sum_{i=1}^n \left\{ \frac{y_i \theta_i - b(\theta_i)}{a_i(\phi)} + c(y_i, \phi) \right\}. \quad (12)$$

Assume that the mean μ_i depends linearly on the covariates through a link function g as follows:

$$g(\mu_i) = \eta_i = \mathbf{X}_i^T \boldsymbol{\beta}.$$

Because the link function is invertible, we can also write

$$\mu_i = g^{-1}(\eta_i) = g^{-1}(\mathbf{X}_i^T \boldsymbol{\beta}).$$

Note that

$$\mu_i = b'(\theta_i), \theta_i = (b')^{-1} \circ g^{-1}(\mathbf{X}_i^T \boldsymbol{\beta}) := h(\mathbf{X}_i^T \boldsymbol{\beta})$$

where

$$b'(\theta_i) = \frac{\partial b(\theta_i)}{\partial \theta_i}, g'(\mu_i) = \frac{\partial g(\mu_i)}{\partial \mu_i}, \text{ and } h'(\boldsymbol{\beta}) = \frac{\partial h(\boldsymbol{\beta})}{\partial \boldsymbol{\beta}}.$$

According to the chain rule, we have

$$\begin{aligned} \frac{\partial L_n}{\partial \beta_j} &= \sum_{i=1}^n \frac{\partial L_i}{\partial \theta_i} \frac{\partial \theta_i}{\partial \beta_j} \\ &= \sum_{i=1}^n \frac{y_i - \mu_i}{\phi} h'(\mathbf{X}_i^T \boldsymbol{\beta}) X_{i,j} := \sum_{i=1}^n (y_i - \mu_i) W_i X_{i,j}, \end{aligned}$$

where

$$W_i = h'(\mathbf{X}_i^T \boldsymbol{\beta}) / g'(\mu_i) \phi.$$

Define $\mathbf{W} = \text{diag}(W_1, \dots, W_n)$, then the gradient is

$$\nabla L_n(\boldsymbol{\beta}) = \sum_{i=1}^n \frac{(y_i - \mu_i) \mu_i'(\eta_i)}{\sigma_i^2} \mathbf{X}_i = \mathbf{X}^T \mathbf{W}(\mathbf{y} - \boldsymbol{\mu}).$$

For the Hessian, we have

$$\frac{\partial^2 L_n}{\partial \beta_j \partial \beta_k} = \sum_{i=1}^n \frac{y_i - \mu_i}{\phi} h''(\mathbf{X}_i^T \boldsymbol{\beta}) X_{i,j} X_{i,k} - \frac{1}{\phi} \sum_{i=1}^n \left(\frac{\partial \mu_i}{\partial \beta_k} \right) h'(\mathbf{X}_i^T \boldsymbol{\beta}) X_{i,j}.$$

Note that

$$\frac{\partial \mu_i}{\partial \beta_k} = \frac{\partial b'(\theta_i)}{\partial \beta_k} = \frac{\partial b'(h(\mathbf{X}_i^T \boldsymbol{\beta}))}{\partial \beta_k} = b''(\theta_i) h'(\mathbf{X}_i^T \boldsymbol{\beta}) X_{i,k}.$$

So,

$$-E[\mathbf{H}_{L_n(\boldsymbol{\beta})}] = \mathbf{X}^T \mathbf{W} \mathbf{X},$$

where $\mathbf{W} = \text{diag}\left(\frac{h'(\mathbf{X}_i^T \boldsymbol{\beta})}{g'(\mu_i)}\right)$. It leads to the Hessian matrix $\mathbf{H}(\boldsymbol{\theta}) = -\mathbf{X}^T \mathbf{W} \mathbf{X}$. Fisher scoring is equivalent to the Newton-Raphson method when we use the canonical link in logistic regression. Since $y_i \in (0, 1)$, $-\mathbf{X}^T \mathbf{W} \mathbf{X}$ is strictly negative definite. When y_i is too close to 0 or 1, weights are close to 0 and $\mathbf{H}$ may have singular values close to 0 and therefore may be computationally singular. The Newton-Raphson algorithm (Green, 1984; Cleveland and Devlin, 1988; Simonoff and Tsai, 1991) iterates according to

$$\begin{aligned} \boldsymbol{\beta}^{(t+1)} &= \boldsymbol{\beta}^{(t)} + (\mathbf{X}^T \mathbf{W} \mathbf{X})^{-1} \mathbf{X}^T \mathbf{W}(\mathbf{y} - \boldsymbol{\mu}) \\ &= (\mathbf{X}^T \mathbf{W} \mathbf{X})^{-1} \mathbf{X}^T \mathbf{W}(\mathbf{y} - \boldsymbol{\mu} + \mathbf{X} \boldsymbol{\beta}^{(t)}), \end{aligned} \quad (13)$$

which is the iteratively reweighted least squares (IRLS) algorithm (Ruppert and Wand, 1994).

Remarks: IRLS solves a generalized linear model in each iteration

$$(\mathbf{X}^T \mathbf{W} \mathbf{X})^{-1} \mathbf{X}^T \mathbf{W} \mathbf{z}^{(t)},$$

where $z^{(t)} = y - \mu + X\beta^{(t)}$ is the residual. When W is symmetric positive definite this is equivalent to the solution of the weighted least squares problem:

$$\min_{\beta} \sum_{i=1}^n \left(W^{1/2} (X_i^T \beta - y_i) \right)^2.$$

Note that in the logistic regression case $g'(\mu) = g(\mu)(1 - g(\mu))$ is never zero, so that the diagonal entries of W are never zero. However, other link functions might lead to degenerate cases with indefinite weighting matrices. When the link function $g(\mu)$ is the identity function and the error follows Gaussian with mean zero and variance one ($N(0, 1)$), then the IRLS algorithm becomes

$$\begin{aligned} \beta^{(1)} &= 0, \\ \mu &= X\beta^{(1)} = 0, \\ z &= \eta + \frac{y - g(\mu)}{g'(\mu)} = 0 + \frac{y - 0}{1} = y, \\ W &= \text{diag} \left(\frac{g'(\mu)^2}{(g'(\mu))^2} \right) = \text{diag}(1^2/1) = I_n, \\ \beta^{(2)} &= 0 + (X^T X)^{-1} X^T y, \end{aligned}$$

which is the ordinary least squares estimator.

Variance heterogeneity

When the residual errors show a trend (e.g., increasing variability as the explanatory variable increases), this can be addressed by modeling the variance as a function of the independent variable or the fitted values. Different methods such as the likelihood ratio test, score test, nonparametric test, and certain modeling approaches can be used for the diagnosis of heteroscedasticity in normal nonlinear regression models (Tsai, 1986; Simonoff and Tsai, 1991; Diblasi and Bowman, 1997; Lin and Wei, 2003). For non-normal models, the test of departure from the nominal dispersion, including over-dispersion and under-dispersion were also discussed (Dean, 1992; Wei et al., 1998).

If variance heterogeneity is ignored, the parameter estimates may not be influenced much, but it may result in severely misleading confidence and prediction intervals (Carroll and Ruppert, 2017). One way of taking into account variance heterogeneity is by explicitly modeling it by formulating a regression model for the variance. For example, Chung and Park (2007) investigated regression models in which the conditional variance of the error is an unscaled function of an integrated time series.

The generalized least squares method (Nelder and Wedderburn, 1972) is typically used for correlated residuals with heterogeneous variances using the IRLS (Eq. 13). Formally, we replace the assumption of the noise distribution $\varepsilon \sim N(0, \sigma^2 I_n)$ with the assumption of the noise distribution as $\varepsilon \sim N(0, \Sigma)$ where $\Sigma = V^{1/2} R V^{1/2}$. Here V is a diagonal matrix of potentially different (heterogeneous) variance terms and R is a correlation matrix. V has a constant diagonal and R can be modeled by a variance function (e.g., $a_i(\phi)$ in an exponential family in Eq. (12)) or an autoregressive-moving-average temporal structure. Additionally, Gaussian processes (Rasmussen, 2003) with the Bayesian nonparametric inference have been widely used for heteroscedastic nonlinear regression in which we have $f \sim N(\mu, K)$. The covariance matrix K has elements $K_{ij} = \kappa(\mathbf{x}_i, \mathbf{x}_j)$, and function κ measures similarity between two observations $\mathbf{x}_i$ and $\mathbf{x}_j$. For example, the radial basis function kernel has $\kappa(\mathbf{x}_i, \mathbf{x}_j) = \exp\{-\|\mathbf{x}_i - \mathbf{x}_j\|^2 / \gamma\}$ with a hyperparameter γ .

Model building

Model building aims at finding more realistic ways to describe the stochastic behavior observed in data. We listed a few widely used models, which are classified by their shape and applied to real data analysis in various fields (Farebrother, 1983).

- Polynomial models. Linear and quadratic polynomial regression have been widely applied to solve real-world data problems for scientists and engineers. Quadratic or higher-order polynomials are curved with respect to the predictors, but they are linear in the parameters so that they can be fitted by using linear regression. However, they tend to overfit the responses with a large number of predictors. As the availability of nonlinear regression algorithms increased, the use of polynomials has sensibly decreased. Linear or quadratic polynomials are mainly used to approximate the observed response within a small range of each predictor for understanding the relationship with the response.
- Concave/Convex curves models. Concave/convex curves describe nonlinear relationships with asymptotes and without inflection points.
 1. Exponential model. The exponential equation describes an increasing or decreasing trend with constant relative rate. The most common parameterization is

$$f(x, \theta) = \theta_1 \exp(\theta_2 x),$$

where the slope of the tangent line through x is θ_2 . Therefore, the response increases by an amount that is proportional to x positively when $\theta_2 > 0$ (exponential growth), and negatively when $\theta_2 < 0$ (exponential decay). The exponential curve is used to describe the growth of a population in unconstrained environmental conditions. The exponential function is nonlinear and can be fitted by using `nls()` or `drm()` functions in R (Team et al., 2018).

2. Asymptotic model. The asymptotic regression model describes a limited growth, where y approaches a horizontal asymptote as $x \rightarrow \infty$. There are several different parameterizations known as the monomolecular growth model (Fekedulegn et al., 1999). The most widely used parameterization is

$$y = \theta_1 - (\theta_1 - \theta_2)\exp(-\theta_3 x) + \varepsilon,$$

where θ_1 is the maximum attainable y , θ_2 is y at $x = 0$, and θ_3 is proportional to the relative rate of y increase while x increases.

3. Negative exponential model. This model can be given by

$$y = \theta_1(1 - \exp(-\theta_2 x)),$$

which has a similar shape to the asymptotic regression, but $y = 0$ when $x = 0$, and is often used to model absorbed photo-synthetically active radiation (Kiniry et al., 1989).

4. Power curve model. The power curve is also known as the Freundlich equation or allometric equation (Thommes et al., 2015) and the most common parameterization is

$$y = \theta_1 x^{\theta_2} + \varepsilon.$$

This curve is equivalent to an exponential curve on the logarithm of x since $\theta_1 x^{\theta_2} = \theta_1 \exp(\log(x^{\theta_2})) = \theta_1 \exp(\theta_2 \log(x))$, and it does not have an asymptote for $x \rightarrow \infty$.

5. Logarithmic model. After x is log-transformed,

$$y = \theta_1 + \theta_2 \log(x)$$

is a linear model with $x > 0$. The parameter θ_2 dictates the shape, as in the exponential equation, Indeed, if $\theta_2 > 0$, the curve is convex up and y increases as x increases. If $\theta_2 < 0$, the curve is concave up and y decreases as x increases.

6. Rectangular hyperbola model. The Michaelis-Menten equation is a rectangular hyperbola, often parameterized as

$$y = \frac{\theta_1 x}{\theta_2 + x} + \varepsilon,$$

which is a convex-up curve and y increases as x increases up to a plateau level. The parameter θ_1 represents the asymptote as $x \rightarrow \infty$, while θ_2 is the x value giving a response equal to $\theta_1/2$. This is because $\theta_2 = x_{50}$ when $\theta_1/2 = \frac{\theta_1 x_{50}}{\theta_2 + x_{50}}$ where x_{50} is the median.

- Sigmoidal curve model. Sigmoidal curves are S-shaped and may be increasing, decreasing, or symmetric around the inflection point. We show a common parameterization.

1. Logistic model. The logistic curve is derived from the cumulative logistic distribution function; the curve is symmetric around the inflection point and it may be parameterized as

$$y = \theta_1 + \frac{\theta_2 - \theta_1}{1 + \exp(\theta_3(x - \theta_4))} + \varepsilon,$$

where θ_2 is the upper asymptote, θ_1 is the lower asymptote, and θ_4 is the x value producing a response half-way between θ_2 and θ_1 . θ_3 is the slope around the inflection point, and it can be positive or negative. Hence, y may increase or decrease as x increases.

2. Gompertz model. The Gompertz curve has the following parameterization

$$y = \theta_1 + (\theta_2 - \theta_1)\exp\{-\exp[\theta_3(x - \theta_4)]\} + \varepsilon,$$

where the parameters have the same meaning as those in the logistic model, but the difference is that this curve is not symmetric around the inflection point.

- Log-logistic models. The sigmoidal response curve is symmetric on the logarithm of x , which requires a log-logistic curve. For example, in biologic assays, the log-logistic curve is defined as follows:

$$y = \theta_1 + \frac{\theta_2 - \theta_1}{1 + \exp\{\theta_3[\log(x) - \log(\theta_4)]\}} + \varepsilon,$$

where the parameters have the same meaning as the logistic model.

1. Weibull-type 1 model. The Weibull distribution is a widely used lifetime distribution in reliability and life data analysis. The type-1 Weibull curve is an alternative for the Gompertz curve like the log-logistic curve is for the logistic curve. The model function is as follows:

$$f(x, \theta) = \theta_1 + (\theta_4 - \theta_1)\{1 - \exp\{-\exp[\theta_2(\log(x) - \log(\theta_3))]\}\}.$$

The parameters have the same meaning as in the sigmoidal curves.

2. Weibull-type 2 model. The type-2 Weibull curve is for the Gompertz curve what the log-logistic curve is for the logistic curve. The equation is as follows:

$$f(x, \theta) = \theta_1 + (\theta_4 - \theta_1) \exp\{-\exp[\theta_2(\log(x) - \log(\theta_3))]\},$$

again with the same parameter interpretation as in the sygmoidal curves.

Simulation data analysis

We compare the nonlinear least squares estimation with different initial values of the parameters in the nonlinear regression using a simulated dataset where the error term ε is not normally distributed. We show that the Bayesian approach is more appropriate to find reliable estimates as well as the confidence regions. The simulation setting is similar to the one shown in Fig. 1. We use the Michaelis-Menten model (Eq. 10) to simulate 100 data points with $\varepsilon \stackrel{i.i.d.}{\sim} \text{Gamma}(10, 0.25)$, $\theta_1 = 100$, and $\theta_2 = 0.05$. The covariates $\mathbf{X}$ are generated from the absolute values of $N(0, 20^2)$.

We implement the least squares method through the `nls()` function in R (Baty et al., 2015). Two sets of starting values for the parameters θ_1 and θ_2 are tried, (10, 3) and (50, 0.1), to validate if least squares estimates can converge to the true values given bad starting values.

Both the estimates and 95% confidence intervals for θ_1 and θ_2 using the least squares and Bayesian approaches are shown in Table 1. With good initial values, both the least squares and Bayesian method give good estimates and confidence regions for the parameters. However, when the starting values are bad, the estimates are far from the true values for both methods. The 95% confidence regions still contain the true values for Bayesian modeling, but the bands are too wide since the posterior samples tend to converge to local optimums.

Further reading

- Levenberg-Marquardt algorithm. The use of the Gauss-Newton algorithm with Levenberg-Marquardt modifications (Levenberg, 1944; Marquardt, 1963) is to speed up the convergence as well as to stabilize the computation for near-singular $\mathbf{J}^T \mathbf{J}$ in the least squares normal equations. The Levenberg-Marquardt method compromises the Gauss-Newton method and the steepest descent method.
- Multicollinearity. This occurs when some columns in the Jacobian matrix $\mathbf{J}$ are highly correlated and leads to an ill-conditioned matrix of normal equations. This implies that the model may be over-parameterized, so that a simpler model or a transformation of the predictors or parameters may be considered.
- Nonparametric and semiparametric regression. If the target of data analysis is to fit the response curve on the explanatory variables, a nonparametric regression could be a better alternative than a nonlinear regression model. However, the fitted curve may be less interpretable. Semiparametric regression which consists of both parametric and nonparametric components is an alternative to nonlinear regression modeling.
- Kernel estimator. A one-dimensional smoothing kernel is any smooth, symmetric function $K: \mathbb{R} \rightarrow \mathbb{R}$ such that $K(x) \geq 0$ and $\int K(x)dx = 1$, $\int xK(x)dx = 0$, $0 < \int x^2 K(x)dx < \infty$. Given a bandwidth $h > 0$, the Nadaraya-Watson kernel regression estimator (Nadaraya, 1964; Watson, 1964) is defined as

$$\hat{f}_h(x) = \frac{\sum_{i=1}^n K\left(\frac{\|x-x_i\|}{h}\right) y_i}{\sum_{i=1}^n K\left(\frac{\|x-x_i\|}{h}\right)} = \sum_{i=1}^n w_i(x) y_i,$$

Table 1 The estimates of θ_1 and θ_2 with the 95% confidence intervals using least squares and Bayesian approach with two different settings of initial values.

Model	Initials	$\theta_1 = 100$	$\theta_2 = 0.05$
NLS	(10, 3)	81.78 (73.94, 89.61)	-0.22 (-0.23, -0.21)
	(50, 0.1)	102.53 (102.38, 102.69)	0.05 (0.05, 0.05)
Bayesian modeling	(10, 3)	84.74 (25.48, 102.67)	-0.25 (-1.18, 0.05)
	(50, 0.1)	102.53 (102.37, 102.69)	0.05 (0.05, 0.05)

where $w_i(x) = \frac{K(\|x - X_i\|/h)}{\sum_{j=1}^n K(\|x - X_j\|/h)}$. Therefore, $\hat{f}_h(x)$ is a local weighted average of the y_i 's.

- Initial values for parameter estimation. For a linear model the Gauss-Newton method finds the minimum in one iteration from any initial parameter estimates. If the nonlinear mean function is nearly linear, the convergence of the Gauss-Newton method is fast and does not depend heavily on the initial parameter estimates. However, as the magnitude of model nonlinearity is large, convergence can be slow or even may not occur, and the resulting parameter estimates may not be reliable. In that case, good initial values are important.
- Differential geometric view. The measures of curvature described above are related to the parameterization. When a normal error assumption is assumed, a Euclidean metric is imposed. Changing the error distribution results in a different metric and geometric structures of the distributions. The study of probability and information using differential geometry is called information geometry. We refer the reader to Amari (2016) for theory and applications of information geometry.

In many educational contexts, data occur in a nested structure. For example, we may measure the achievement level of a child in a particular subject matter. That child is located (nested) within a particular class of students, and we might predict that the child's performance would have been different had she been in a different class of students. Further, the child's class may be one of many within a particular school, and that school may be one of many within a school system, which is located within a larger educational or political unit (e.g., county, state, and region). Each level of the structure may have its own characteristics that influence the achievement of the child. Hierarchical linear models (and more general models, to be discussed later) are designed to properly model influences on outcome variables at all levels of such a hierarchy, including the proper handling of data dependencies created by the nested structure. (Note that not all nesting produces a multilevel model; only when both levels are random effects is this true. For example, people nested within treatments, as in a typical ANOVA, do not result in the type of model discussed here because levels of treatment are typically fixed in number and are not a random sample from a population of treatments.)

In this article, we describe a variety of models that are designed to accommodate a nested data structure. Some models are linear, but others are nonlinear; some involve nesting of people within higher-level units (such as classes), while other models are applicable to repeated measures that are nested within individuals (including longitudinal studies). We begin with a very simple example, and then show how the principles involved can be used to expand the scope and type of models that may be used. These principles are all expansions or generalizations of those used in ordinary least squares (OLS) regression; often, the models can be viewed as a series of regressions for different levels of the data structure. Those unfamiliar with regression should read the article on univariate linear regression in this volume before reading the rest of this one.

Although we will not discuss it in detail, these methods also resolve the problem known as aggregation bias. It has been well known that correlations among variables at a higher level (e.g., measures on states) do not equal (and may be opposite in sign to) correlations among variables at the individual level. (A related problem that arises in categorical data analysis is known as Simpson's paradox.) Multilevel models are constructed so that inferences can be made at the right level, whichever level that happens to be for the problem at hand.

We discuss two examples of multilevel models. The first example is for a situation in which students are nested within colleges, and we wish to predict academic performance from one student-level and one college-level variable. The second example considers longitudinal data, where a series of observations is made on each person over a period of time. Here, the nesting is of a different sort: Observations (over time) are nested within individuals.

Example 1: two levels, one predictor at each level, linear model

For a first example, assume that the administration in 10 colleges in a particular country wants to see how well scores on an academic-achievement test given to all students in the last year of secondary school predict performance of students in their first year of college. If we consider each college separately, we may imagine that within each college, researchers fit a regression model to the data; the equation for school j would then be:

$$Y_{ij} = \beta_{0j} + \beta_{1j}X_{ij} + r_{ij}$$

In this equation, Y represents the grade of a student after the first year of college, X represents the score of the student on the secondary school-achievement test, i is used to refer to a specific student, and j to refer to a specific school. The coefficients are as in a linear regression model, except that each school has its own intercept (β_{0j}) and slope (β_{1j}).

As we shall be examining the intercept and slope of each school, and modeling them, it is important to be sure that these are quantities of interest. For the slope, there is ordinarily no issue (except perhaps multiplication or division by a constant in order to make a one-unit change more easily interpreted). In order to make the intercept meaningful, we will often have to transform X . One common strategy is centering, which means to create a new variable by subtracting the mean of X from each observed value of X . (For this article, we assume that the mean is computed for the whole data set, not for each college individually; this is called grand mean centering.) In any regression, the intercept represents the predicted value of Y when all predictors have a value of 0; therefore centering X will cause the intercept in each college's regression equation to equal the predicted value of Y for a student who is average on X (based on students from all included colleges). Using the exact sample mean is not necessary; sometimes, it is more important to use a round number for ease of interpretation. For example, if the mean is 497, it might be easier to subtract 500. Or, if a score of 600 is typically required for admissions, one might subtract 600 from all X values instead.

In addition to subtracting some value from X , one might also want to control the scaling further. In the United States, for example, where Scholastic Aptitude Test (SAT) scores have a mean near 500 and a standard deviation near 100, one might divide by 100 so that a one-unit change in the transformed variable is more meaningful than a one-unit change on the original scale. This makes the slope more easily interpreted (and sometimes improves numerical stability.) From this point on, we will assume that X has been suitably scaled.

The term r_{ij} is a residual, indicating that the students' scores on the secondary school test will typically not predict their grades in college perfectly. The variance of the residuals in each college can differ among schools, but often modeling is begun by assuming that it is the same in each; we will denote the within-school residual variance by σ^2 , in which we do not use a subscript for college (j).

The intercepts and slopes will vary from college to college; some of this variation is just sampling variability due to using a sample of students within each college, but the other variability is due to true differences among colleges. The true variability in intercepts will be denoted by τ_{00} , and the true variability in slopes will be denoted by τ_{11} . (There is also a covariance between the intercepts and slopes, denoted τ_{01} , but this is seldom of much interest.)

If τ_{00} and τ_{11} are small, then the intercepts and slopes do not vary much among colleges, and one prediction equation will work equally well in each. The colleges will gain by knowing this, because now their prediction equation is known with greater precision due to the contribution of information from other colleges. Of course, unless the colleges are very similar, it is unlikely that both τ_{00} and τ_{11} will be small, which leads to a consideration of two issues: First, can we explain, based on characteristics of the colleges, why some have larger and others smaller intercepts and/or slopes? Second, even though the colleges differ, can we still use information from other colleges to help improve prediction in each college?

We may believe that characteristics of the colleges will have some relationship to either the intercept or the slope of their prediction equations. For example, it may be that schools differ in the difficulty of their courses, or in their grading standards. These may affect the intercepts or slopes. One might use the college's average value on X as a proxy for selectivity or difficulty; this could be a predictor for intercepts and/or slopes. Another possible measure would be the selection ratio, that is, the proportion of applicants who are admitted to the college.

We will now write the model for variability among colleges out more formally. The equations, which will first be presented without predictors, are:

$$\beta_{0j} = \gamma_{00} + u_{0j}$$

$$\beta_{1j} = \gamma_{10} + u_{1j}$$

The first equation says that the intercept in a particular college (j) is equal to some overall average plus a deviation of that college's intercept from the overall average. The second equation expresses the same idea for the slopes from each college. The variances of the residuals (u_{0j} in the first equation and u_{1j} in the second) are the values τ_{00} and τ_{11} mentioned previously. In this instance, they are called unconditional residual variances, because they are not conditioned (dependent) on any college-level predictors. When we analyze the data we will obtain estimates of both the mean intercept and slope (called fixed effects in most software) and the variances of the residuals (called random effects in most software, though it is the u_{ij} s that are random variables).

Now suppose that the residual variances are large enough that we believe it worthwhile to try to account for some of their variation by using a college-level variable such as proportion of applicants admitted. In realistic applications, there are often many potential variables, and variables that help predict differences in intercepts may not be the same variables that help predict differences in slopes. In this simple introduction, however, we will use only one such variable, which we will call W ; individual values of W are denoted W_j , with the subscript j indicating that the value of W will vary across colleges.

The extended model at the college level will now consist of the following equations:

$$\beta_{0j} = \gamma_{00} + \gamma_{01}W_j + u_{0j}$$

$$\beta_{1j} = \gamma_{10} + \gamma_{11}W_j + u_{1j}$$

The variances τ_{00} and τ_{11} of the residual terms u_{0j} and u_{1j} now represent conditional variances; that is, the variances remaining after accounting for variation in intercepts and slopes using information provided by the predictor W . These variances should now be smaller than in the unconditional model if W proves to be a good predictor, and measures analogous to R -square in the usual regression context may be calculated.

Multilevel models are very much like ordinary regression models in many ways: the outcome variable may be continuous or categorical. If continuous, it may be normally distributed or have some other distribution (e.g., exponential for survival models). If the dependent variable is categorical, models similar to logistic regression (for binary outcomes) or its extensions to polytomous or ordinal outcomes are possible. The right-hand side of any of the equations may require polynomial coding (e.g., the square and cube) for continuous predictors, dummy variables (or other coding methods) for categorical predictors, and product terms for interactions. The model may be intrinsically nonlinear, so that more complex models must be fit. We deal briefly with some of these issues later, and other articles have more details.

Example 2: repeated measures and longitudinal data

In many educational applications, people are measured more than one time. In some cases, these measurements extend over a long period of time; measurements may be daily, weekly, monthly, or yearly, for example. In other cases, the time sequence is not of great importance; for example, most models for test scores do not take into account that some items are administered before others. In either case, we can use the concept of nesting to reconceptualize the model for this type of data: we view observations as being nested within an individual. (In some instances, it might seem more natural to view time of observation as crossed with individuals, but this viewpoint is not usually considered in the multilevel literature, because doing so would reduce the utility of the model in many common situations, as we hope will become apparent shortly.)

As an example, suppose that a researcher wants to examine the growth of children's ability to sight-read words. Each month during the school year, she has every child in a class attempt to read a list of 20 words, and counts the number of words that the child can correctly read. We will treat the number of words read as if it were a continuous outcome variable to simplify the discussion in this section, and will later deal with the complexities that this type of outcome necessitates. The researcher wants to model the number of words read by each child as a function of the number of months into the school year. The time variable may be coded in a number of ways; one might be to start the variable Months at 0 for the first measurement period, and increase by one for each month. Another approach would be to use 0 for the last period of measurement, and number preceding periods as -1 , -2 , etc. Each possible choice determines the meaning of the intercept in the model. Again, for simplicity we will use a linear model, but realize that a straight line is unlikely to be a perfect description of such growth; we write the equation for each student as follows:

$$Y_{ij} = \pi_{0j} + \pi_{1j}M_{ij} + e_{ij}$$

where the subscript j is used to represent the individual student, i is used to represent a measurement occasion, Y_{ij} is the number of words read correctly by student j at occasion i , M_{ij} is the number of months (on whatever scale is chosen; here we will assume 0 is used for the first time of measurement) for measurement of student j at occasion i , and e_{ij} is the residual. The intercept π_{0j} and slope π_{1j} are different for each student, and again we will allow these to be predicted by variables at the higher level, which in this case is the individual student. For example, boys and girls may start at different levels, and they may progress at different rates. We may represent this by the following level-2 equations, in which F is equal to one for females and zero for males:

$$\pi_{0j} = \beta_{00} + \beta_{01}F_j + r_{0j}$$

$$\pi_{1j} = \beta_{10} + \beta_{11}F_j + r_{1j}$$

Of course the structure of all of these equations is exactly the same as the case in the first example where students were nested within colleges; only the context has changed. In these equations, the intercepts β_{00} and β_{10} represent the beginning number of words read (π_0) and the rate of change in words per month (π_1) for an average male (i.e., $F = 0$) in the study. The slopes in these equations, β_{01} and β_{11} , represent the difference in beginning number of words read and rate of change for females as compared to males. Again, the choice of coding makes a difference; gender could be coded in other ways, which would change the interpretation of each of the coefficients in these equations. The residual terms represent the amount by which the true values of π_{0j} and π_{1j} differ from that predicted for the average male or female.

This method of representing the model has several advantages over other methods. Most importantly, from a conceptual point of view, this is a model for each individual's growth pattern and for deviations of individuals from the average pattern. The focus is on the individual, rather than a group. As a consequence of this focus, in principle (and at present, in practice also) missing data are not a problem, as long as the cause for missingness is not related to the outcome variable. Each child could have a different pattern of months during which he or she was measured, and in fact the times of measurement do not even have to follow a common pattern. A child could be measured at months 1.25, 3.75, and so on, rather than exactly at the beginning of each month—the model remains the same. (Of course, in practice one must measure each individual a reasonable number of times, and with those times spaced in a reasonable way, in order to have accurate estimates of that child's growth pattern, but this is another matter.)

Generalized linear and nonlinear models

Two general categories of complications frequently arise with multilevel models. As mentioned previously, not all dependent variables are continuous, and not all continuous variables have a normal distribution. In addition, not all relationships are linear, so nonlinear models must sometimes be considered. This section briefly describes some approaches to each issue.

In the second extended example described, the outcome was the number of words read correctly from a list of 20 words presented to the student. Equivalently, one might calculate the percentage or proportion of the list that was read correctly. If proportions were not extreme (e.g., if most were between 0.2 and 0.8), then using these in a model with a normal distribution might be a good approximation to the correct analysis. A more accurate approach would be to consider each word as a trial, and the number correct as coming from a binomial distribution with an underlying probability of success for each trial that is constant across words. (An even more accurate model would allow words to have varying difficulties, and possibly to differ in other ways also, as in item-response theory. Often the simplifying assumption of equal difficulty is a good enough approximation to work well in practice.)

The binomial model is closely related to a more widely known model, logistic regression. For these models, the outcome that is modeled is usually the logarithm of the odds of a correct response, commonly called the logit of the probability of a correct response. The right-hand side of the level-1 equation for individual responding still has a linear form in these models; the left-hand side is the transformed value $\ln(\omega/(1-\omega))$, also denoted $\text{logit}(\omega)$ in some sources, where ω is the probability of a student responding correctly. The model for each individual is written in the following form:

$$\ln\left(\frac{\omega_{ij}}{1 - \omega_{ij}}\right) = \pi_{0j} + \pi_{1j}M_{ij}$$

where ω_{ij} is the expected (not observed) probability of person j answering correctly during month i . The residual is not explicitly listed in this equation; instead, we state that $Y_{ij} \sim \text{Binomial}(20, \omega_{ij})$; that is, the observed number of words correctly read has a binomial distribution based on 20 trials, with probability ω_{ij} of being correct on each trial.

This is an example of a generalized linear model; these are extensions of linear models that include a linear model, a transform of the dependent variable, and a distributional form that is more general than a normal distribution. In this case, the logit is the transformation and the binomial is the distributional form.

Another example requiring the use of generalized linear models is when the outcome is a count, but the count is not the number of successes in a fixed number of trials, or it is a generally small count out of a very large number of fixed trials (in which case we are using an approximation to the binomial distribution). A researcher might count the number of times a student shows an aggressive behavior toward classmates, or the number of times the student raises his or her hand for the attention of the teacher rather than responding without being called on. If the period of observation is the same for each student and time of observation, then generally the Poisson distribution provides the simplest probability model for counts. A slight extension is required when the time of observation varies, so that the model is for the rate of behavior per period of time (number of hand raises per hour, e.g., when the time of observation may vary between 5 and 20 minutes). If F represents the expected number of acts and Z represents the amount of time for an observational period, so that F/Z is a rate per unit time, the level-1 equation can be written in the following form:

$$\ln(F_{ij} / Z_{ij}) = \pi_{0j} + \pi_{1j}M_{ij}$$

As with the binomial model, there is no explicit error term in the equation because the count variable in the equation is an expected rather than observed frequency, and in this case it has a Poisson distribution.

A related model with the same form is the discrete-time survival model, in which we model the influences on the occurrence of an event. In education, we might wish to determine factors affecting whether, and if so when, a student in college will drop out. Modeling whether or not the student drops out involves an ordinary logistic regression (or possibly with students nested within colleges if we observe many colleges). But to model the length of time to dropout is slightly more complicated. We observe each student over a series of semesters, and note whether he or she has dropped out or is still enrolled for that semester. The main aspects of this situation that are different from others with a binary outcome in each time period are that (1) drop out can only occur during one period, and (2) the sequence of observations can be stopped (censored) due to graduation so that the event we are looking for (dropout) may not be observed for that individual. It may not be obvious, but information from students who never drop out is nonetheless useful. Survival models developed in somewhat parallel ways in three areas: medicine (for obvious reasons), engineering (where they are generally known as failure time models), and sociology (where they are known as event history models).

Shrinkage estimates

In the original example, predicting grades of students in college based on their grades in secondary school, each of the 10 researchers could do a study and estimate a slope and intercept for their own college. But the 10 colleges, while not identical, should be similar enough so that each researcher can use the information from all 10 colleges to estimate the slope and intercept in their college. Using a phrase common in this type of situation, they can each borrow strength from related data sets. This generally will shrink their

estimate of the intercept and slope toward the average intercept and slope. The amount of shrinkage depends on how well their own parameters are estimated; if they have little data, shrinkage will be large, but if they have a great deal of data on their own school, shrinkage will be small.

One can also adjust shrinkage for characteristics of the college. Perhaps large colleges have different slopes or intercepts than small colleges; if so the size of the college (or a function of it, such as the logarithm) can be used as a predictor. (Centering or other scaling of these predictors is also recommended for more useful interpretation of parameters.)

Note that the more similar the colleges are, the more is gained from shrinkage estimates. The extreme instance, with identical colleges, would make the random effect variances zero, and the situation would revert to one large sample, with more accurate estimates due to the larger sample size applying to each. Even if the colleges are not identical, if the differences among them are explained by their characteristics, then the residual variances are small and result in more accurate estimates of the individual colleges' intercepts and slopes.

Meta-analysis

A situation in which it is not obvious that multilevel models can be applied is meta-analysis. In meta-analysis, a large number of studies about a topic are summarized by a measure of effect size, and by other characteristics of the study (age of subjects, whether a randomized design was used, etc.). The objective is to determine what the average effect size is, whether it varies (beyond sampling variability) from study to study, and if so whether study characteristics can be used to predict that variability. If we view subjects as nested within studies, it is easy to see that this falls into the realm of multilevel models, but with the individual level data missing (i.e., we only see summary statistics for the study as a whole). Most programs for multilevel models (and some additional specialized programs) can perform such analyses.

Bayesian estimation

Multilevel models have two types of parameters: Those generally called fixed effects, represented in this article by γ_{ij} , and the variances of random effects, represented by τ_{ij} and σ^2 . Broadly speaking there are two kinds of estimation methods for these parameters in hierarchical models: Frequentist and Bayesian. Frequentist methods (such as maximum likelihood and least squares) treat parameters as fixed unknowns; Bayesians treat parameters as random variables that have distributions (or at least our beliefs about them have distributions). Frequentist results are consequently estimates of the parameters and standard errors, which tell how accurate the estimates are. Bayesians summarize their beliefs about the parameters in terms of probability distributions.

Bayesian methods have several advantages. They take into account all uncertainty; in particular the estimation of regression parameters takes into account uncertainty about the variance parameters. This is important when there are a small number of higher-level units, because their variance is poorly estimated. Bayesian methods also lead naturally to shrinkage estimators, and handle missing data in a more natural way than frequentist methods. The interpretation of interval estimates is more natural for Bayesians: There is a 95% chance that the parameter value is in the 95% credible interval (analogous to a frequentist confidence interval). Other probabilities can be calculated that cannot be using frequentist methods; for example the probability that an effect is greater than zero (or any other number). Software for general Bayesian modeling is somewhat involved to use; popular packages include BUGS/WinBUGS/OpenBUGS, jags, and Stan. Common models can be dealt with more simply, for example with the brms or MCMCglmm packages in R. For further information on Bayesian inference, see the entry "Bayesian Statistical Analysis" and [Kruschke and Vanpaemel \(2015\)](#).

Three underutilized applications of hierarchical models

The most common applications of hierarchical models are (i) people nested in groups, (ii) longitudinal data (observations over time nested in people), and (iii) meta-analysis (people nested in studies). There are other applications that are less-often utilized, but quite useful when they are appropriate.

Complex repeated measures designs

Suppose you are examining papers written by a group of people, and rating each on how many errors of a particular type were made out of the number of opportunities to make them. Different people have different number of opportunities, so the structure of the responses is different for each person. These subjects, in turn, are measured on a variable thought to be predictive of making that type of errors (e.g., age or gender). This would be difficult or impossible to analyze from a typical repeated measures perspective, but is straightforward using hierarchical models. Note this is different from the usual application that emphasizes growth modeling (that is, in this case we are not modeling behavior as a function of time/age.) For more information on such designs, see [Schonfeld and Rindskopf \(2007\)](#).

More generally, consider any situation in which there is a data set for each individual, and a model for each person's behavior. Then one can consider what the average of each parameter is across individuals, how much variation there is across individuals in

the parameters, and whether that variation can be explained as a function of person-level characteristics. Single case designs common in psychology can be analyzed in this manner; in those studies time is a nuisance variable rather than a variable of substantive interest (see e.g., [Rindskopf and Ferron, 2014](#)).

Modeling panel results (repeated surveys)

If a survey or a testing program is repeated at regular intervals, a model may be desired for each administration. These could be fit separately to each set of data for a time point, in which case the estimates of similar quantities (parameters) are not strengthened by what should be similar estimates in the other years. On the other hand, complete pooling of data, making the coefficients the same in each time point, is probably not correct either. A hierarchical model allows each coefficient to be estimated separately, but with support from data at other time points. This could be as simple as making each parameter in a model a random effect, or modeling a linear or quadratic time change for parameters.

For example, suppose a survey were administered every year, and we wish to fit the same regression model every year. Our model for person i in year j is:

$$Y_{ij} = \beta_{0j} + \beta_{1j}X_{1ij} + \beta_{2j}X_{2ij} + r_{ij}$$

At one extreme, if we believed that the coefficients were the same in every year, we could pool data from all years and fit one equation. At the other extreme, if we believed coefficients could change wildly from year to year, we would fit each year's data separately. But if we believed that the coefficients were similar, though not identical, we would fit level 2 equations, here represented as having a linear trend over time:

$$\beta_{0j} = \gamma_{00} + \gamma_{01}t_j + u_{0j}$$

$$\beta_{1j} = \gamma_{10} + \gamma_{11}t_j + u_{1j}$$

$$\beta_{2j} = \gamma_{20} + \gamma_{21}t_j + u_{2j}$$

where t represents time, perhaps scaled so that 0 is the current time. The time effect may be modeled as quadratic if it is believed that the parameters do not change in a linear fashion over time. Additional characteristics of years (such as whether a pandemic was taking place) could also be entered. This use of HLM is similar to having people nested within groups, except people are nested within time-structured groups, similar to some repeated measures data.

Parameter shrinkage (and reducing effects of multicollinearity) by modeling the structure of regression parameters

In regression a frequent problem is collinearity, the high correlation among predictors. Many possible solutions to this problem have been suggested, some of which include shrinking the (standardized) coefficients toward zero. One such technique is known as ridge regression, and another is the LASSO. Such methods can be put in the multilevel framework. This can be more general than similar methods such as ridge regression, because all coefficients are not necessarily shrunk toward the same value (such as zero or the mean).

The meaning of "hierarchical" is somewhat different in these models. People (or observations) are not nested; the hierarchy is one of parameters. The parameters in which we are interested (here the regression coefficients) are modeled at the next level of the hierarchy of parameters, which is of smaller dimension than the original set of parameters. [Lindley and Smith \(1972\)](#) were the first to suggest a Bayesian version of ridge regression and related models (in addition to the more common version of multilevel models we have discussed).

Recommended reading

Several excellent textbooks are available to learn more about multilevel models. [Raudenbush and Bryk \(2002\)](#), whose notation is similar to that used here, and [Goldstein \(2011\)](#) cover a wide range of material on these models. Each of these also is associated with software to fit these models, HLM ([Raudenbush et al., 2019](#)) for the former and MLWin ([Rasbash et al., 2020](#)) for the latter. Other introductory books include [Hox et al. \(2018\)](#) and [Snijders and Bosker \(2012\)](#). [Gelman and Hill \(2007\)](#) have a unique viewpoint, and many interesting approaches not found elsewhere. Other references in the reading list include more advanced works, as well as specialized references on various aspects of multilevel models.

Summary and conclusion

When units are nested within higher level units, multilevel modeling should be used for three major reasons: (1) it is the correct analysis (which ordinarily would be a sufficient reason), (2) viewing the model in this way leads to insights that are otherwise

elusive about relationships, and (3) we avoid certain perplexing problems, such as aggregation bias. Multilevel models can be used not only in obvious situations such as when we have children in classes (and or schools), but also where subjects are nested within studies (meta-analysis), or where observations are nested within people (repeated measures and longitudinal studies). Using these models enables us to estimate effects within each level of a study, as well as between levels. Specialized software is readily available, and several major statistical packages now include the capability to fit multilevel models.

Introduction

Valid inference requires proper methods to handle discrete data. Categorical data consist of counts or discretely measured variables. Examples of categorical variables include race or ethnicity, responses to a multiple-choice question, status of an online purchase, students' letter grades, gender, responses to survey items, graduation status, and whether an individual receives a vaccination. The methods described in this chapter are for analyses where a categorical variable is the response, outcome, or dependent variable; predictor or explanatory variables are either categorical or continuous. The levels of categorical variables can be either nominal (e.g., type of high school attended) or ordinal (e.g., letter grade).

Whether a variable is nominal or ordinal depends on context. For example, whether you received a vaccine seems to be inherently nominal. Either you have or have not received a vaccine. However, if the question "Have you received a COVID-19 vaccine?" is an item on a scale developed to measure a person's perceived susceptibility or the consequences of getting sick, the "yes" and "no" categories are ordered concerning what the scale is measuring.

In this chapter, we use examples of two categorical variables. Fundamentals here include contingency tables, sampling processes, sampling distributions, estimation of probabilities with hypothesis testing, measures of association, and testing for relationships using statistics based on different distributions.

Notations

Throughout this chapter, notations for categorical variables are in Roman letters, and parameters of models and distributions are represented by lower-case Greek letters. For instance, the data can be presented as a two-way contingency table with two categorical variables. In this situation, X and Y denote categorical variables; a cross-classification of these two variables is shown in a contingency table, where n_{ij} is a count or frequency within the cell (i, j) (i.e., row i and column j), n_{i+} and n_{+j} are the row and marginal column totals, and n is the total sample size. When there are more than two rows or columns, the numbers of rows and columns are denoted by I and J , respectively. μ represents the mean of a variable (X or Y), π denotes a probability, p is a sample proportion. For example, μ_{ij} , π_{ij} and $p_{ij} = n_{ij}/n$ represent the mean, probability, and sample proportion for cell (i, j) , respectively. df is the short form for degrees of freedom.

Sampling processes

The data about fatal shootings from on-duty police officers in the United States from January 2015 to December 2020, compiled by the Washington Post, were cross-classified in **Table 1** for two variables: gender (female, male) and race (non-white, white). We

Table 1 Counts of fatal police shootings cross-classified in a two-way table by race and gender.

	Woman	Man	Row Totals
Non-white	98	2892	2990
White	155	2552	2707
Column Totals	253	5444	5697

dropped three incidents that involved young children. The values within each cell are the frequencies of cases for each combination of gender and race, and the numbers in the margins are totals by row and by column.

Incidents in **Table 1** are assumed to be independent of each other, and each incident falls into only one contingency table cell. In the theory of population sampling, the data in **Table 1** reflect the *Poisson sampling*, in which each population unit has a certain probability of being included in the sample data (Särndal et al., 1992). In this case, the marginal frequencies and the total number of observations are not bounded or fixed by design; therefore, cell proportions and the row and column proportions reflect actual probability distributions in the population, which can differ.

Table 2 shows an example of independent *Bernoulli sampling*, a special Poisson sampling case. The probability of being sampled into a category for each subject is the same in this sampling process. Specifically, this probability remains 0.5 because there are only two categories for the corresponding variable. Data in **Table 2** offer an example. They come from a phase-3 clinical trial of the Moderna vaccine for COVID-19. In this trial, 15,210 subjects were randomly assigned to the placebo and the vaccine groups (Baden et al., 2021), and they were later classified as being “symptomatic” or “asymptomatic.” In **Table 2**, the row margins are fixed by design.

Sampling distributions

When binomial sampling is used, as shown in **Table 2**, the row distributions are independent, and row margins follow a *binomial distribution*. Specifically, the *binomial distribution* is helpful for modeling counts or proportions of a variable (or event) that has two categories (or outcomes), such as students’ success or failure in a college course and getting head or tail when flipping a coin. The binomial distribution assumes that (1) there is a fixed total of independent trials for this event, in which each trial has two outcomes (known as a *Bernoulli trial*), and that (2) the probability of the targeted outcome (e.g., “success”) is the same for each trial. A Bernoulli trial with the quality of (2) is also known as an *identical trial*.

The mean and variance of the probability of the outcome Y in a fixed number of Bernoulli trials are

$$E(Y) = n\pi, \text{VAR}(Y) = n\pi(1 - \pi), \quad (1)$$

where n denotes the total number of trials and π denotes the probability of the occurrence of the targeted in one trial. The probability of having the targeted outcome occurring in y trials follows the binomial probability mass function:

$$P(y) = \frac{n!}{y!(n-y)!} \pi^y (1 - \pi)^{n-y}, y = 0, 1, 2, \dots, n \quad (2)$$

For example, if the probability of selecting a student enrolled in the National School Lunch Program in a school district is 0.2, then the probability of having seven students who are enrolled in this program, out of a random sample of 10 students in this school district, is $P(7) = \frac{10!}{7!(10-7)!} 2^7 (1 - .2)^{10-7} = 0.0008$, which is 0.08%. It is worth noting that the sample size matters here to ensure accuracy in making statistical inferences: The fixed total n should be at least 10 when π equals 0.5 to make the binomial distribution symmetric. This requirement is necessary to meet normality, a fundamental assumption undergirding frequentist statistical modeling. The required minimum gets larger when π gets closer to 0 or 1 to achieve this symmetric, bell-shaped distribution. In this case, we say the sample size is “large enough” and see the binomial distribution as a normal one.

In a more generalized case, if the “response” or outcome variable (i.e., symptomatic) has three or more categories (e.g., none, mild, severe), we would get contingency tables with three or more columns, and each row would follow a *multinomial distribution*. The multinomial distribution assumes that (1) there is a fixed total of independent trials for this event, in which each trial has more

Table 2 A 2×2 table of counts of treatment group by COVID-19 infection.

	Asymptomatic	Symptomatic	Row Totals
Placebo	15,025	185	15,210
Vaccine	15,199	11	15,210
Column Totals	30,224	196	30,420

than two outcomes, and that (2) the probability of each outcome (e.g., none, mild, severe) is the same for each trial. When the probability of each outcome is denoted by π_j (such that we have $\pi_1, \pi_2, \dots, \pi_j$), we must have $\sum_j \pi_j = 1$. Given the fixed total of identical trials, n , we must have the numbers of occurrences for each outcome, denoted by y_j (such that we have $y_1, y_2, \dots, y_j$), meet $\sum_j y_j = n$. Hence, the probability of having y_1 trials with the first outcome, y_2 trials with the second outcome, ..., and y_j trials with the last outcome follow the multinomial probability mass function below:

$$P(y_1, y_2, \dots, y_j) = \left(\frac{n!}{y_1! y_2! \dots y_j!} \right) \pi_1^{y_1} \pi_2^{y_2} \dots \pi_j^{y_j}, y_j = 0, 1, 2, \dots, n \quad (3)$$

Evidently, the binomial distribution described above is a special case of the multinomial distribution in which $j = 2$.

The *Poisson distribution* is typically used for counts or proportions of an event occurring randomly over time or space. It helps analyze the categorical data, such as the number of students that completed an activity online in an hour of a day, and the number of people who arrive at a university gym within 5 min during Day 1 of a new semester, as shown in Table 3. This distribution assumes the following:

(1) The numbers of people arriving at the university gym in non-overlapping time intervals are independent, (2) the probability of precisely one person arriving at a university gym, π , is proportional to the length of the time interval, and (3) the probability of two or more people arriving at the university gym in a sufficiently short interval is essentially 0. This Poisson probability distribution is unimodal and skews to the right. Its mean and the variance (of the probability of occurring) for the outcome Y are equal to π :

$$E(Y) = \text{VAR}(Y) = \pi. \quad (4)$$

For the outcome Y occurring in y trials, the Poisson probability mass function is

$$P(y) = \frac{e^{-\mu} \mu^y}{y!}, y = 0, 1, 2, \dots, n. \quad (5)$$

As π increases, the Poisson distribution becomes more symmetrical and closer to a bell shape.

Types of probability

For two-way tables, we distinguish between three types of probability: joint probability, marginal probability, and conditional probability. The *joint probability* of X and Y is the probability that an observation falls into cell (i, j) , a combination of categories from two variables. For example, given the fatal police shooting in Table 1, we can calculate maximum likelihood estimates for the joint probabilities, as shown in Table 4. For example, the estimated joint probability that the victim was a non-white woman equals $\hat{\pi}_{11} = 0.017$.

In some situations, our focus may be on the row or column margin, investigating the *marginal probability*. The marginal probabilities equal $\pi_{i+} = \pi_{i1} + \pi_{i2} + \dots + \pi_{ij}$ for row margins, and $\pi_{+j} = \pi_{1j} + \pi_{2j} + \dots + \pi_{ij}$ for column margins. For instance, using the police shooting data in Table 1, we can obtain maximum likelihood estimates of marginal probabilities of victims being non-white or white, or of marginal probabilities of victims being woman or man. They are shown in the row and column margins of Table 3, respectively. This marginal probability of victims being non-white is $\hat{\pi}_{1+} = 0.525$, and this marginal probability of victims being white is $\hat{\pi}_{2+} = 0.475$.

The *conditional probability* refers to the probability of an outcome conditioning on the probability of another outcome. For the two-way contingency tables, the conditional probability of the category j of one variable given the category i of another variable equals

$$\pi_{j|i} = \pi_{ij} / \pi_{i+}. \quad (6)$$

Given the vaccine data in Table 2, we can calculate conditional probabilities for each row and column, shown in Table 5. When the conditional probabilities for the two rows are approximately the same for a column (i.e., either the asymptomatic or symptomatic group), we may conclude that the vaccine is not effective for the asymptomatic/symptomatic group.

Table 3 Example: number of people who arrive at a university gym during day 1.

Estimation of the unknown probability

Estimation method: maximum likelihood estimation

As hinted, our probability estimates presented in [Tables 4–5](#) are *maximum likelihood estimates*. In the practice of categorical data analysis, the probability parameter π in the binomial, multinomial, or Poisson distribution is often unknown. In this case, we need to *infer* the value of the unknown based on the knowns like n and y , which researchers often have control of in a research design. In an inferential method, a (point) *estimate* is a value derived from some observed data. It is an inference of the *estimator*, which can be seen as a random variable that follows a specific sampling distribution. In the most popular inferential method, *maximum likelihood estimation* method, the *estimate* is a value of the *estimator* following a *likelihood function*. The estimate maximizing this function is known as the *maximum likelihood estimate*, and it can be interpreted as the *most likely* value of the unknown parameter given the values of known parameters.

The maximum likelihood estimation method is popular because of an important property: Its estimator of probability (e.g., π) can be approximated by a sample proportion (e.g., $\hat{p}$), which follows a normal distribution when the sample size is large (i.e., the *Law of Large Numbers*, which claims that a proportion in a sample, $\hat{p}$, gets closer to the proportion in the population, p , as the sample size increases). This normality minimizes standard errors in parameter estimation. In other words, the maximum likelihood estimators have good “large-sample behaviors.” Other estimators tend to have relatively large standard errors because they usually do not follow a normal distribution. The mean and the variance of the sampling distribution of the maximum likelihood estimator π are the same as that of the binomial distribution for p :

$$E(\hat{\pi}) = E(\hat{p}) = \pi, \text{VAR}(\hat{\pi}) = \text{VAR}(\hat{p}) = \frac{\pi(1 - \pi)}{n}. \quad (7)$$

The likelihood function is mathematically equivalent to the joint probability mass function evaluated at the observed values ([Hogg et al., 2015](#)). For n trials that follow the binomial distribution, when the targeted outcome shows up $y_1, y_2, \dots, y_n$ times, this joint probability mass function is

$$P(y_1, y_2, \dots, y_n) = \prod_{i=1}^n \pi^{y_i} (1 - \pi)^{n - y_i} = \pi^{\sum y_i} (1 - \pi)^{n - \sum y_i}. \quad (8)$$

When treated as a function of π , the above function is known as the likelihood function $L(\pi)$:

$$L(\pi) = f(y_1; \pi) f(y_2; \pi) \dots f(y_n; \pi) = \pi^{\sum y_i} (1 - \pi)^{n - \sum y_i}. \quad (9)$$

When solving this function, we can obtain the maximum likelihood estimate of the unknown parameter π , denoted by $\hat{\pi}$. This $\hat{\pi}$ equals the observed proportion $\hat{p}$ of an event in a sample, expressed as

$$\hat{\pi} = \hat{p} = \frac{y}{n}. \quad (10)$$

Hypothesis testing

The maximum likelihood estimate of the unknown parameter in a population, as described above, is based on a sample. One sample is generally not a perfectly accurate reflection of the whole population. For example, while we know the probability of

obtaining a head when flipping a coin is $\pi = 0.5$ (i.e., the population parameter), we may get three heads when flipping a coin ten times (i.e., a sample) instead of five heads. This sample statistic about the probability of getting a head is $\hat{\pi} = 3/10 = 0.3$, which is not 0.5. The difference between a sample statistic and the population parameter is called *sampling error* or *margin of error*. In this example about flipping a coin, the sampling error is 0.2 (i.e., from 0.5 to 0.3).

Considering the existence of the sampling error, *hypothesis testing* is commonly used as a decision-making process to draw inferences about the population based on the sample data. It is about rejecting one of two *hypotheses* related to a research question: the *null hypothesis* and the *alternative hypothesis* (also known as the scientific/research hypothesis). In the prior example about flipping a coin, we can set two competing hypotheses about whether the sample statistic is close enough to the population parameter, corresponding to a two-sided hypothesis test. The null hypothesis is

$$H_0 : \pi = .5. \quad (11)$$

The alternative hypothesis is

$$H_1 : \pi \neq .5. \quad (12)$$

In hypothesis testing, *p-value* is the probability of observing the data at least as extreme as the observed sample, given that the H_0 is true. The *alpha level*, also known as *level of significance* or *Type-I error rate*, is the probability of rejecting the null hypothesis when the null is true; it can be seen as the acceptable error level.

To examine whether the sample statistic is close enough to the population parameter, we check whether the difference between the two is *statistically significant*. If yes, we shall reject the null hypothesis and go with the alternative hypothesis, concluding that the sample statistic is not close to the population parameter. By “statistically significant,” we mean the corresponding *p-value* is *lower* than the alpha level. How can we obtain the *p-value* then? Researchers use the *standard normal distribution* for converting the difference between the sample statistic and the population parameter into a *z score* and then into a *p-value*. In the previous example about flipping a coin, the standard error of the population parameter $\pi = 0.5$ is calculated as follows:

$$SE = \sqrt{\text{VAR}(\hat{\pi})} = \sqrt{\frac{\pi(1-\pi)}{n}} = \sqrt{\frac{.5(1-.5)}{10}}. \quad (13)$$

With this standard error, the difference between the sample statistic and the population parameter can be converted into a *z score*:

$$z = \frac{\hat{\pi} - \pi}{SE} = \frac{.3 - .5}{\sqrt{\frac{.5(1-.5)}{10}}} = -1.265, \quad (14)$$

which positions the sample statistic in a standard normal distribution, with which we can find the *p-value* is .898 for $z = -1.265$. When setting the alpha level at 0.05, which is common in educational research, we see the *p-value* 0.898 is not statistically significant, and so we fail to reject the null hypothesis and conclude that the sample statistic 0.3 is close enough to the population parameter 0.5.

As an alternative to the *p-value*, a *confidence interval* is a range of values centered around the sample statistic for hypothesis testing. *Confidence level*, $(1-\alpha) \times 100\%$, defines the width of this range. It is the probability that this range contains the actual value of the population parameter, associated with the alpha level. For example, when the alpha level is 0.05, the confidence level is 95%. The following formula is used to construct this confidence interval for the population parameter π :

$$CI = \hat{\pi} \pm z_{\alpha/2}(\widehat{SE}), \quad \widehat{SE} = \sqrt{\frac{\hat{\pi}(1-\hat{\pi})}{n}}, \quad (15)$$

where $\hat{\pi}$ is the sample statistic. If the confidence interval contains 0, we fail to reject the null hypothesis and conclude that the statistic $\hat{\pi}$ is not statistically significant; if not, we reject the null hypothesis. Using the prior example, we get $\widehat{SE} = \sqrt{0.3(1-0.3)/10} = 0.145$, $z_{\alpha/2} = z_{0.025} = 1.960$, and so the confidence interval is $CI = 0.3 \pm 1.960 \times 0.145 = (0.02, 0.58)$. Because this interval does not contain 0, we reject the null hypothesis and conclude that the estimate 0.3 is statistically significant at the 0.05 level.

Broadly speaking, there are three pillars in the literature about hypothesis testing, and all of them can use a likelihood function to infer the population parameters. They are namely the likelihood-ratio test, the Wald test, and Rao's score test. All three tests are asymptotically equivalent under the null hypothesis. In other words, if the sample size is very large, we would not expect to see a noticeable difference among them. However, if the sample size is small to moderate, the values of the three statistics will diverge. The Wald test is the least reliable when sample size is small, and the likelihood ratio test and the score test are preferred in this case.

What is specified above is *Rao's score test*. In the *likelihood-ratio test*, a ratio of two maximum likelihood estimates is used as the test statistic, called the *likelihood-ratio test statistic*. It is

$$\chi^2 = -2\ln\left(\frac{l_0}{l_1}\right) \quad (16)$$

In this test statistic, l_0 is the maximum likelihood estimate of the parameter when H_0 is assumed to be true, and l_1 is the maximum likelihood estimate over all possible parameter values. In this case, l_1 is at least as large as l_0 . This test statistic takes

the natural log transform with the coefficient 2, as this conversion makes the statistic approximate a *chi-square* statistic, easier for computation. The corresponding *p*-value of this test statistic is the right-tailed probability of the chi-square distribution with $df = 1$.

In the *Wald test*, we evaluate the unrestricted standard error of the estimate of the parameter $\hat{\pi}$, *SE*, by substituting the maximum likelihood estimate for the unknown parameter in the formula of the true standard error (e.g., $SE = \sqrt{\hat{\pi}(1 - \hat{\pi})/n}$, because π follows the binomial distribution). The confidence interval in the Wald test using this *SE* is known as the *Wald confidence interval*. The test statistic in the Wald test is z^2 , which takes the form in Eq. (14), with the standard error being evaluated via the maximum likelihood estimation. It approximately follows a chi-square distribution with $df = 1$. The *p*-value in this Wald test is the right-tailed probability for z^2 in this chi-square distribution. In this test, the distributions for hypothesis testing are often *normal distributions* or *chi-square distributions* when the sample size is large enough.

Measures of association

The two most common measures of association for categorical variables are the odds ratios and Pearson's correlation coefficient. In this chapter, we primarily use the odds ratio as a measure and definition of association.

Odds ratio

Odds are the ratio of two conditional probabilities. For example, the odds of category *i* given column category *j* equal

$$odds = \pi_{ij} / (1 - \pi_{ij}). \quad (17)$$

Using the data in Table 1, the observed odds that a male victim was non-white (vs. white) equals

$$\frac{\hat{\pi}_{non-white|man}}{\hat{\pi}_{white|man}} = \frac{p_{12}/p_{+2}}{p_{22}/p_{+2}} = \frac{n_{12}}{n_{22}} = 2892/2552 = 1.133. \quad (18)$$

The probability of the victim being a non-white man is 1.133 times the probability of the victim being a white man. That is, non-white males were more likely to be shot than white males. For women, the odds equal $98/155 = 0.632$.

The ratio of odds, known as *odds ratio*, ranges from 0 to positive infinity. When the odds ratio is 1, it indicates the odds are equal, and so no relationship exists between the two variables (e.g., race and gender, as the row and column variables). Let θ_{i^*,jj^*} represent the odds ratio of two row categories *i* and *i** and two column categories *j* and *j**. Then the odds ratio equals $\hat{\theta}_{12,12} = 1.133/0.632 = 1.792$ in our example. It says that the *odds* that a victim was a non-white for men is 1.792 times the odds for women. It is worth noting that the odds ratio refers to ratios of odds and not to probabilities, as it would be wrong to state that "the probability of the victim being non-white for men is 1.792 times the probability for women."

Odds ratios can be computed when we calculate a "cross-product ratio" with joint probabilities:

$$\theta_{ii^*} = (\pi_{ij}\pi_{i^*j^*}) / (\pi_{i^*j}\pi_{ij^*}). \quad (19)$$

If we switch the odds in the numerator and denominator, we get $0.632/1.133 = 1/1.792 = 0.558$, and the interpretation would "flip": The odds that a victim was a woman for non-white victims is 0.558 times that for white victims.

Pearson correlation coefficient

The *Pearson correlation coefficient* measures the linear relationship between pairs of variables, which requires numerical codes for categories of each variable. For example, when two survey question items contain the unique responses "strongly disagree," "disagree," "agree," and "strongly agree," we use integers 1, 2, 3, and 4 to code these responses and denote these responses with u_s and v_s , respectively for two question items, where *u* and *v* denote the items and $s = 1, 2, 3, \dots, n$, indexing individual respondents. Thus, if Respondent 1 chooses "disagree" on one item, the response is $u_1 = 2$; if this respondent chooses "agree" on the other item, the response is $v_1 = 3$. Given this coded data, we can set a contingency table with *I* rows and *J* columns corresponding to unique responses to the two items for calculation. Alternatively, we can organize the data in the respondent by item format, displaying all individual respondents' responses in two columns corresponding to the two items. In the latter case, the formula for computing correlation is

$$r_{XY} = s_{XY} / (s_X s_Y) = \frac{\sum_{s=1}^n (u_s - \bar{u})(v_s - \bar{v})}{\sqrt{\sum_{s=1}^n (u_s - \bar{u})^2} \sqrt{\sum_{s=1}^n (v_s - \bar{v})^2}}. \quad (20)$$

where s_{XY} denotes the covariance between the two items, s_X and s_Y denote the standard deviation of the two items, respectively, $\bar{u}$ and $\bar{v}$ denote the means for the two items. For dichotomous variables, (20) is referred to as the *phi coefficient*. The choice of codes makes a difference for variables with more than two categories; we may choose the codes leading to the largest possible correlation,

which can be found from correspondence analysis. For the police shooting data in [Table 1](#), the correlation between gender and race is $r = -0.059$.

Tests of no association

We discuss tests for three possible null hypotheses: independence, homogeneous distributions, and linear relationship. The tests differ regarding the hypothesis being tested and thus the conclusions. After presenting the test statistics, we give examples of tests for nominal and ordinal variables.

Chi-square test statistics

Two common tests statistics have sampling distributions that are approximately chi-square for large sample sizes, requiring five or more counts per cell to ensure the shape of the distribution is chi-square. The two statistics are *Pearson's chi-square statistic*,

$$X^2 = \sum_i \sum_j \frac{(n_{ij} - \hat{\mu}_{ij})^2}{\hat{\mu}_{ij}}, \quad (21)$$

and the *likelihood ratio chi-square statistic* or *deviance*,

$$G^2 = 2 \sum_i \sum_j n_{ij} \log \left(\frac{n_{ij}}{\hat{\mu}_{ij}} \right), \quad (22)$$

where $\hat{\mu}_{ij}$ is the estimated expected frequency in cell (i, j) . Note that Pearson's chi-square statistic X^2 is an integral part of Pearson's correlation: $|r_{XY}| = \sqrt{X^2/n}$.

Both X^2 and G^2 equal 0 when $n_{ij} = \hat{\mu}_{ij}$ for all the cells (i.e., the observed frequencies equal the estimated expected frequencies). For testing independence and homogeneous association, specified below, X^2 and G^2 have the same value for the estimated expected frequency $\hat{\mu}_{ij} = n_{+j} n_{i+}/n$. That said, because the logic for arriving at $\hat{\mu}_{ij}$ differs in the sampling design, these two test statistics can lead to with different conclusions.

Independence

When the margins of a table are not fixed, we may run a test of independence to check if there is a relationship between variables. The null hypothesis of independence is $H_0 : \pi_{ij} = \pi_{i+} \pi_{+j}$ for all i and j , and the alternative hypothesis is $H_a : \pi_{ij} \neq \pi_{i+} \pi_{+j}$ for at least some combination of i and j . Estimated expected frequencies equal $\hat{\mu}_{ij} = n_{i+} n_{+j}/n$. If the null hypothesis is true (and cell counts > 5), then (21) and (22) have approximately chi-square distributed with $df = (I-1)(J-1)$.

For [Table 1](#), testing whether victims' gender and race are independent yields $X^2 = 20.068$ and $G^2 = 20.137$ with $df = (2-1)(2-1) = 1$ and the p -values < 0.01 . The data leads us to the conclusion that gender and race are related. The strength and nature of the dependence, as reflected by the odds ratio, are given in (18).

Homogeneous distributions

When the data follow independent binomial or multinomial distributions, we may be interested in whether the conditional distributions of the response variable are the same (i.e., homogeneous). The null hypothesis is $H_0 : \pi_{j|i} = \pi_{+j}$ or in terms of frequencies, $H_0 : \mu_{j|i} = \pi_{+j} n_{i+}$.

Using the clinical trial data in [Table 2](#), we test whether the distribution of participants receiving the placebo is the same as that of participants receiving the vaccine and get $X^2 = 155.47$, $G^2 = 187.88$ with $df = 1$ and the p -values < 0.01 . These values align with what we find with the odds ratio, which shows a discrepancy between the placebo group and the vaccine group: The odds of people receiving the vaccine are 17.01 times the odds of people receiving the placebo for the asymptomatic group.

Test of linear association

For ordinal variables, there are more powerful association tests that use the order of categories. The *Mantel-Haenszel statistic* is

$$M^2 = (n_{++} - 1)r^2, \quad (23)$$

where r is Pearson's correlation coefficient defined in (3). The hypotheses are $H_0 : \rho = 0$ and $H_a : \rho \neq 0$. M^2 follows a chi-square distribution with one degree of freedom. [Table 6](#) is a cross-classification of responses to two items of the *General Social Survey 2018*. The two items are "In general, would you say your quality of life is ..." and "In general, what would you rate your physical health?". The possible responses are "Excellent," "Very good," "Good," "Fair," and "Poor." To test whether physical health and

Table 6 Ordinal data for two survey questions in *General Social Survey 2018*.

Quality of life	Physical health					Row Totals
	Excellent	Very good	Good	Fair	Poor	
Excellent	221	160	66	29	2	478
Very good	120	410	328	81	11	950
Good	29	71	341	172	27	640
Fair	7	5	40	138	34	224
Poor	1	1	2	11	22	37
Column Totals	378	647	777	431	96	2329

quality of life are related, we use equally spaced integers from 1 to 5 for coding response categories, and obtain $r = 0.599$, $M^2 = 834.937$, and $p\text{-value} < 0.01$. The data support the conclusion of a linear relationship.

Generally speaking, to test a relationship, we needed $(I - 1)(J - 1)$ non-redundant odds ratios to characterize the association between two variables completely. Given our example, this number equals $(5 - 1)(5 - 1) = 16$. Making use of the ordering categories, we can summarize the association using one single statistic, r or M^2 , which is more powerful than X^2 and G^2 in (21) and (22).

Concluding remarks

This chapter scratches the surface of categorical data analysis, part of which overlaps with another chapter in this book about generalized linear models. For comprehensive coverage, a good starting place is Agresti (2019). Most statistical software programs have the functionality to analyze categorical data, including RStudio with R packages named “binom,” “Epi,” and “MASS.”

Introduction

Univariate linear regression models, or just linear regression models, describe how the values of a response variable vary when values of the predictors vary. Linear regression models require that the response variable be continuous (and normally distributed), and the variation of the response observations around the regression line must be approximately constant. However, many situations do not meet these criteria. For example, many response variables are counts or proportions, and for many continuous variables the variation increases as the mean of the response variable increases (that is, the variance is a function of the mean). In these cases, another approach is to use generalized linear models (GLMs). GLMs apply for a wide variety of response variables, and unite many other commonly-used statistical models (such as logistic regression) under a common structure, which enables a common discussion of estimation, inference and residual analysis.

Definition

GLMs have two components: The probability function describing the variation in the values of the response variable (the random component), and a function connecting the mean of the response variable with the values of the predictors (the structural component).

The probability functions that describe how the response variable y is distributed (the random component) have a common structure; collectively, these distributions are called exponential dispersion models (EDMs). EDMs include normal distributions, Poisson distributions (for modeling *counts*), binomial distributions (for modeling *proportions* of a total) and gamma distributions (for modeling right-skewed positive continuous data). Some other distributions, such as the negative binomial and the Weibull, are not EDMs, but are sufficiently closely related to be used in a GLM-like manner.

The probability function for all distributions in the EDM family can be written in the form

$$f(y; \theta, \phi) = a(y, \phi) \exp \left[\frac{y\theta - \kappa(\theta)}{\phi} \right].$$

In this expression, θ (the *canonical parameter*) is a known, invertible function of the mean μ (specifically $\mu = \kappa'(\theta)$). The known function $\kappa(\theta)$ is called the *cumulant function*, and ϕ is a positive *dispersion parameter*. The variance of the EDM is $\text{var}(Y) = \phi \kappa''(\theta) = \phi V(\mu)$, where $V(\mu)$ is called the *variance function* (Table 1). The variance function uniquely identifies the distribution within the EDM family. This common structure allows general statements to be made about all GLMs for fitting models, inference and diagnostic analysis.

[☆] *Change History:* January 2021. P. K. Dunn updated and expanded the text initial sections of the text, changed Example 1, and slightly edited Examples 2 and 3 and the remaining text.

Table 1 Common EDMs and their variance function, dispersion parameter, commonly-used link function, and unit deviance (from which the deviance can be computed). For the binomial distribution, y represents the proportion of “successes” out of m independent trials, where m is known.

EDM	Variance function, $V(\mu)$	ϕ	Commonly-used link function	Unit deviance $d(y, \mu)$
Normal	1	σ^2	$\eta = \mu$ (identity)	$(y - \mu)^2$
Poisson	μ	1	$\eta = \log \mu$ (logarithmic)	$2\{y \log(y/\mu) - (y - \mu)\}$
Binomial	$\mu(1 - \mu)$	1	$\eta = \log \frac{\mu}{1-\mu}$ (logistic)	$2\left\{y \log\left(\frac{y}{\mu}\right) - (m - y) \log\left(\frac{m-y}{m-\mu}\right)\right\}$
Gamma:	μ^2	ϕ	$\eta = \log \mu$ (logarithmic)	$2\{-\log(y/\mu) + (y - \mu)/\mu\}$

Since θ is a known, invertible function of μ , the probability function can also be written directly in terms of the mean μ as

$$f(y; \mu, \phi) = b(y, \phi) \exp \left[-\frac{d(y, \mu)}{2\phi} \right]$$

where $d(y, \mu)$ is called the **unit deviance**. The notation $y \sim EDM(\mu, \phi)$ denotes that the response variable y has a distribution in the EDM family with mean μ and dispersion parameter ϕ .

GLMs are *linear* models, meaning that the predictors combine linearly in the structural component. For each of the $i = 1, 2, \dots, n$ observations, the p predictor variables combine in the form

$$\eta_i = \beta_0 + \beta_1 x_{1,i} + \beta_2 x_{2,i} + \dots + \beta_p x_{p,i} = \mathbf{x}_i^T \boldsymbol{\beta}$$

where $x_{j,i}$ is the i th observation for the j th predictor variable, $\mathbf{x}_i$ is the vector of predictor variables for observation i , and $\boldsymbol{\beta}$ is the vector of length $p + 1$ of unknown regression parameters (and β_0 is called the *intercept*). η is called the *linear predictor*. The predictor values may involve transformed variables (for example, a predictor may take the form $\log x$), categorical variables (using indicator variables), or interactions between variables. The relationship between μ and η is defined by

$$\eta_i = g(\mu_i)$$

for all $i = 1, 2, \dots, n$ observations, where the function $g(\cdot)$ is called the *link function*. The link function must be a differentiable, monotonic function. A suitable choice of link function for many GLMs is the logarithmic function (Table 1) because this ensures $\mu > 0$ for any value of η . For example, the logarithmic link function is almost always used with a Poisson distribution since then $\eta = \log(\mu)$ and hence $\mu = \exp(\eta)$, and so $\mu > 0$ without needing to place restrictions on the values of η (and hence β). Using the logarithmic link function also means that additive effects in η have a multiplicative effect on y . Linear regression models use the identity link function $\mu = \eta$. Binomial EDMs require special link functions to ensure $0 < \mu < 1$, since then μ represents a proportion.

The complete GLM can be written as

$$\begin{cases} y_i \sim EDM(\mu_i, \phi) & \text{(The random component)} \\ g(\mu_i) = \beta_0 + \beta_1 x_{1,i} + \beta_2 x_{2,i} + \dots + \beta_p x_{p,i} & \text{(The systematic component)} \end{cases}$$

Fitting a GLM is not the same as fitting a linear regression model with a transformed response variable. For example, a GLM fitted using a log link has the form $\mu_i = E[y_i] = \exp \eta_i$ (where $E[\cdot]$ means “expected value”). Transforming the response variable and fitting a linear regression model leads to a model with systematic component $\mu_i = E[\log y_i] = \eta_i$; that is, the GLM models the means directly, whereas the regression model models the logarithm of the response variable. Note that there are $p + 1$ unknown regression parameters in the systematic component.

Fitting: estimating the regression parameters

The estimates of the regression parameters $\boldsymbol{\beta}$ are almost always maximum likelihood estimates (MLEs), written $\hat{\boldsymbol{\beta}}$. For a GLM based on a normal distribution, the MLEs are the same estimates obtained using least-squares. For other EDMs, the MLEs are found numerically using the iteratively reweighted least squares algorithm (IRLS). Since EDMs all have a similar structure, a general algorithm for fitting GLMs can be developed that applies for all GLMs. The algorithm generally converges rapidly.

The IRLS algorithm for estimating $\boldsymbol{\beta}$ only depends on the mean and variance of the EDM, and not the full EDM distribution. In addition, the value of ϕ is not needed for computing $\hat{\boldsymbol{\beta}}$, so (if necessary) the value of ϕ can be estimated separately, hence estimating ϕ is discussed later. This estimate $\hat{\boldsymbol{\beta}}$ can then be used to compute the fitted values $\hat{\mu} = g(\hat{\eta}) = X\hat{\boldsymbol{\beta}}$ where X is the $n \times (p + 1)$ matrix of predictor values, and $\hat{\mu}$ and $\hat{\eta}$ are vectors of length n .

The estimate of the variance of $\hat{\beta}$, written $\widehat{\text{var}}(\hat{\beta})$, is easily computed from the results of the IRLS fitting algorithm. The standard error of $\hat{\beta}_j$, written $\text{s.e.}(\hat{\beta}_j)$, is the j th diagonal element of the square root of $\widehat{\text{var}}(\hat{\beta})$.

Fitting a GLM using software requires the user to nominate the EDM and the link function to use, the response variable, and the list of predictors. All major statistical software packages can fit GLMs.

Evaluating models

Competing GLMs can be compared using a measure of discrepancy between the observations y_i and the fitted means $\hat{\mu}_i$. One discrepancy measure is the **residual deviance**

$$D(y, \hat{\mu}) = \sum_{i=1}^n d(y_i, \hat{\mu}_i)$$

where $d(y, \mu)$ is called the **unit deviance** (Table 1). The **scaled residual deviance** is defined as $D^*(y, \hat{\mu}) = D(y, \hat{\mu})/\phi$. The residual deviance is often just written as D and the scaled deviance as D^* . The distribution of the scaled deviance approximately follows a chi-squared distribution (with $n - (p + 1)$ degrees of freedom), and is related to the log-likelihood of the EDM (Dunn and Smyth, 2018, p. 236).

Another discrepancy measure is the **Pearson statistic** X^2 :

$$X^2 = \sum_{i=1}^n \frac{(y_i - \hat{\mu}_i)^2}{\text{var}(\hat{\mu}_i)} = \sum_{i=1}^n \frac{(y_i - \hat{\mu}_i)^2}{\phi V(\hat{\mu}_i)}.$$

Both the deviance and Pearson statistics are equivalent to the residual sum-of-squares for normal distributions: $\sum_{i=1}^n (y_i - \hat{\mu}_i)^2$. If the value of ϕ is unknown, an estimate is used. Software generally reports the value of the deviance (or scaled deviance) after fitting a model.

Inference

Since GLMs all have a similar structure, inference can be developed in general terms. Competing models can be compared by observing the *changes* in the discrepancy for nested models. If the *change* in residual deviance is used, this is equivalent to a likelihood-ratio test (LRT).

Consider two models: a larger model L with residual deviance D_L with $p_L + 1$ unknown parameters in the linear predictor, and a second (smaller) model S with $(p_S + 1) < (p_L + 1)$ unknown regression parameters and residual deviance D_S . Model S is *nested* in Model L if the regression parameters in Model S are a subset of those in model L ; then $D_L \leq D_S$.

If the value of ϕ is known, then $(D_S - D_L)/\phi$ has an approximate χ^2 distribution, with $p_L - p_S$ degrees of freedom. When the value of ϕ is unknown and is estimated, then

$$\frac{(D_S - D_L)/(p_L - p_S)}{\tilde{\phi}}$$

has an approximate F -distribution, with $(p_L - p_S, n - (p_L + 1))$ degrees of freedom (where $\tilde{\phi}$ is some estimate of ϕ).

Regression coefficients can be tested individually for significance using *Wald tests*. "The test statistic $(\hat{\beta}_j - \beta_j)/\text{s.e.}(\hat{\beta}_j)$ for testing if the regression coefficient has the value β_j has an approximate normal distribution when the value of ϕ is known (or an approximate t -distribution when ϕ is estimated)." The standard errors of the regression parameters are computed as a by-product of fitting the GLM, as noted above, so values of the Wald test statistic (and the corresponding p -value) are readily computed and reported by software.

For linear regression models only, the LRT and Wald tests are equivalent with exact distributions. For all other EDMs, the tests are approximate only, but the distributional assumptions are better, in general, for the LRTs. All major software packages include facilities for conducting LRTs and Wald tests.

Estimating ϕ

Although an estimate of ϕ is not needed to estimate β , a value of ϕ is needed to compute D^* and $\text{s.e.}(\hat{\beta}_j)$. The MLE of ϕ is not usually used since it is difficult to compute and has poor properties anyway (Dunn and Smyth, 2018); usually, the mean deviance or the Pearson estimate is used.

The mean deviance estimator of ϕ for a model with $p + 1$ estimated regression parameters in the linear predictor η is $D(y, \hat{\mu}) / (n - (p + 1))$, where D is the value of the residual deviance for the model. The Pearson estimate of the dispersion parameter is $X^2 / (n - (p + 1))$, where X^2 is the value of the Pearson statistic for the model. Different software may, by default, report either the Pearson or deviance estimate of ϕ .

Evaluating model fit

Since GLMs all have a similar structure, common methods of evaluating the model (diagnostic analysis) can be developed. However, the standard residuals used in linear regression (that is, $r_i = y_i - \hat{\mu}_i$ for each observation) do not make sense in the GLM context, since the variation of $\hat{\mu}_i$ is a function of the value of $\hat{\mu}_i$. Instead, Pearson and deviance residuals are commonly used. *Pearson residuals* are defined as

$$r_{P,i} = \frac{y_i - \hat{\mu}_i}{\sqrt{\text{var}(\hat{\mu}_i)}}$$

where the denominator rescales the residuals so that the variance is approximately constant for all $\hat{\mu}_i$. Notice that $X^2 = \sum r_{P,i}^2$.

By analogy to the Pearson residuals, write $D = \sum r_{D,i}^2$. Then, the *deviance residuals* are $r_{D,i} = \sqrt{d(y_i, \hat{\mu}_i)}$ and where $r_{D,i}$ takes the sign of $y_i - \hat{\mu}_i$. Both the Pearson and deviance residuals have approximate normal distributions (and so behave similar to the familiar residuals from linear regression models), but normality is not guaranteed. Hence, if the deviance or Pearson residuals do not show approximate normality, either the model is inadequate or the model is adequate but the residuals are simply non-normally distributed. This non-normality can be very evident when using EDMs with discrete values of y (i.e., binomial and Poisson EDMs). A better choice of residual, suitable even for discrete EDMs, is to use quantile residuals (Dunn and Smyth, 1996) which are always approximately normally distributed (apart from sampling variation) whenever the correct EDM is used.

Other statistics used for diagnostic analysis—such as hat values, and influence measures such as Cook's distance—also have approximate analogies with linear regression models in the context of GLMs.

All major software packages compute deviance and Pearson residuals, other diagnostic statistics, and can plots these statistics. R allows the computing of quantile residuals (using the `statmod` package; Smyth et al., 2020).

Example 1: binomial GLM

The most common type of GLM is the binomial GLM. The data summarized in Table 2, obtained from the Australian Bureau of Statistics web page (<https://www.abs.gov.au>), contains the number of four-year-old students enrolled at school in Queensland, Australia, in 2019, classified by Sex, School Type and indigenous status. Consider modeling the *proportion* of First Nation students, say μ_i , using a *binomial* distribution, where m_i is the total number of students in each category. This assumes that each student is independent of other students, which may not be true.

A simplistic systematic component is $\log[\mu_i / (1 - \mu_i)] = \beta_0$, which (unrealistically) states that the proportion of First Nation students is not related to the Sex of the student or the School Type. The link function used here is the *logit link*, and the model is commonly called a *logistic regression model*. Other link functions can be used (such as the *probit link*), but the logistic link function is commonly-used and allows interpretation in terms of odds and odds ratios: $\mu / (1 - \mu)$ represents the odds that a randomly-chosen student is First Nation, so the systematic component can be written as $\log\text{-odds} = \beta_0$, or $\text{odds} = \exp(\beta_0)$. This shows that the regression coefficients are related to the *odds* of the event of interest (here, the odds that a student is First Nation). All popular statistical software can fit this GLM. Using R (R Core Team, 2020), the systematic component is $\log[\mu_i / (1 - \mu_i)] = -2.351$. This suggests that the *odds* that a student is First Nation is $\exp(-2.351) = 0.0953$. Using the data in Table 2 directly, the odds are $6027/63252 = 0.0953$ also.

Table 2 The number of students in Queensland schools in 2019, classified by the sex of the student, the type of school and whether the students are First Nation or not. Note: The cohort sizes are $m = m_1 + m_2$.

Sex of student: x_1	School type: x_2	Number of First Nation students: m_1	Number of non-First Nation students: m_2	Proportion First Nation students: y_i
Females	Government	2540	21,219	0.1069
Males	Government	2734	22,574	0.1080
Females	Non-government	391	9496	0.0395
Males	Non-government	362	9963	0.0351
	Totals	6027	63,252	0.0870

More realistically, the predictors are incorporated into the model. Categorical variables are included through numerical coding: the predictor x_1 can be coded such that 0 represents females and 1 represents males; the predictor x_2 can be coded using 0 for government schools, and 1 for non-government schools. (This coding is arbitrary.) Then a possible systematic component is

$$\log[\mu_i / (1 - \mu_i)] = \beta_0 + \beta_1 x_{1,i} + \beta_2 x_{2,i}$$

where x_1 and x_2 take the values 0 or 1 as appropriate, as described above. Using the R function `glm()` with `family = "binomial"`, the following estimates are found (output slightly edited):

Coefficient	Estimate	Std. error	z-value	p-value
Intercept $\hat{\beta}_0$	-2.113	0.0202	-104.7	<0.0001
Sex (female: 0; male: 1): $\hat{\beta}_1$	-0.006564	0.027147	-0.242	0.809
School type (gov: 0; non-gov: 1): $\hat{\beta}_2$	-1.135	0.0399	-28.456	<0.0001
Null deviance: 1033.1798 on 3 degrees of freedom				
Residual deviance: 2.9359 on 1 degree of freedom				

The output shows that the systematic component of the model is

$$\log[(\mu_i / (1 - \mu_i))] = -2.133 - 0.006564x_{1,i} - 1.135x_{2,i}$$

where the values of x_1 and x_2 are defined above. The random component is $y_i \sim \text{Bin}(\mu_i)$.

The p -values (final column), from a Wald-test, show that the School Type is significantly associated with the proportion of First Nation students, but the Sex of the student is not. Alternatively, a LRT can be conducted by fitting a binomial GLM *without* School Type as a predictor. This yields a binomial GLM with a residual deviance of 1033.17 (with 2 df). The *change* in the residual deviance between these two models is substantial ($1033.17 - 2.9359 = 1030.2$), by adding just one extra parameter (that is, on $3 - 2 = 1$ degree of freedom). This produces a very small p -value after referring to a χ^2_1 distribution, which means the model *with* School Type as a predictor is a far better model than the model *without* this predictor.

The deviance residuals (one for each row in Table 2) are -0.4497, 0.4358, 1.1280, and -1.1276. While deviance residuals do not follow a normal distribution exactly, none of these residuals are large in value (say, greater than three in absolute value), so they raise no concerns with the fitted model.

Example 2: rate model

Consider the (hypothetical) data in Table 3. The number of incidents in eight schools are shown along with the numbers of students and an average school test score. We would like to know if the number of incidents is related to the test score. However, larger schools naturally will tend to generate more incidents.

The response variable is a count, best modeled using a Poisson distribution. The number of incidents out of the school size μ/N could be modeled using a binomial distribution. Instead, we will model the counts using a Poisson distribution with the log link (to ensure a positive mean μ), since the counts may be of greater interest (for example, it may inform the number of support staff employed). The systematic component of the model is:

$$\log(\mu / N) = \beta_0 + \beta_1 x$$

where we have omitted the subscripts i for convenience. Rearranging:

$$\log \mu = \log N + \beta_0 + \beta_1 x$$

Table 3 The number of incidents occurring in schools of given sizes and average test scores.

Incidents, y	7	5	1	5	2	1	5	2
Number of students, N	985	850	241	495	838	616	759	842
Score, x	32	74	44	20	50	73	48	36

This is called a *rate model*. The term $\log N$ will result in multiplying the rate at which the incidents occur by the number of students as we might wish here. This term has no regression coefficient (or, rather, it is fixed at one). Such a term is called an *offset*. The remaining part of the predictor is linear in the score, x . All popular statistical software can fit this GLM. Using R, the following estimates are found (output slightly edited):

Coefficient	Estimate	Std. error	z-value	p-value
Intercept $\hat{\beta}_0$	-4.6703	0.5319	-8.78	<0.0001
Score	-0.0139	0.0114	-1.22	0.22
Null deviance: 8.0380 on 7 degree of freedom				
Residual deviance: 6.4944 on 6 degree of freedom				

The negative coefficient for Score of -0.0139 suggests that the rate of incidents decreases with increasing test Scores. The z -statistic of -1.22 can be used to test the significance of this effect (p -value: 0.22) but, as before, using the change in the residual deviance is more reliable. Here the null model (fitted with only the intercept) is the appropriate smaller model, with a *null deviance* of 8.0380. The test statistic is $8.0380 - 6.4944 = 1.5436$. Comparing to a χ^2_1 distribution, the p -value is 0.21, as there is one degree of freedom difference between the two models. Either test suggests there is insufficient evidence of a relationship between test scores and the rate of incidents.

Example 3: categorical data

A GLM approach is also useful for modeling categorical data. Consider the data in [Table 4](#) from [Faraway \(2016\)](#). Subjects from the 1996 US National Election Study (NES) study were cross-classified by political identification (PID) and level of education.

Suppose we consider the counts as Poisson distributed with mean μ_{ij} and use a GLM with log link

$$\log \mu_{ij} = \mu + \text{PID}_i + \text{Education}_j$$

where the both predictors are considered as nominal (unordered) factors, each with seven levels. The rate at which observations fall in each of the cells will be some overall mean rate multiplied by a parameter reflecting the level of party identification, times another parameter representing the level of education. This is equivalent to claiming that PID and level of education are independent. The estimated parameters for the factor levels represent the relative proportions of observations falling in each row or column of the data. These are usually not of interest, and say nothing about the *relationship* between the two factors. Instead, the interaction terms, not the main effects, are usually of interest as they model the dependence between the factors.

Fitting the main-effects model gives a residual deviance of 40.7 on 36 degrees of freedom. A model that allows dependence between the two factors would require a separate parameter for each cell. Then, the number of parameters would equal the number of data points, so the model would fit perfectly with a deviance of zero on zero degrees of freedom. If we compare this latter saturated model to the independence model above, the difference in deviance is 40.7 on 36 degrees of freedom resulting in a p -value of 0.27. Hence, we prefer the smaller model which represents independence of the two factors.

Traditionally, the test for independence uses a Pearson's χ^2 which we might compute here as the sum of the squared Pearson residuals, giving a value of 38.8 again on 36 degrees of freedom. Hence, the outcome of the test is similar to the deviance-based test.

The analysis so far has not used the ordinality of both factors (they have been treated as nominal). One way to accommodate these in the model is by using scores. We assign scores u_i and v_j to the rows and columns such that $u_1 \leq u_2 \leq \dots \leq u_7$ and $v_1 \leq v_2 \leq \dots \leq v_7$.

Table 4 A subset of subjects drawn from the 1996 US NES study, cross-classified by political identification and level of education.

	MS	HS dropout	HS	Some college	CC degree	BA degree	MA degree
Strong democratic	5	19	59	38	17	40	22
Weak democratic	4	10	49	36	17	41	23
Independent democratic	1	4	28	15	13	27	20
Independent	0	3	12	9	3	6	4
Independent republican	2	7	23	16	8	22	16
Weak republican	0	5	35	40	15	38	17
Strong republican	1	4	42	33	17	53	25

Notes: MS: 8 years of education or less; HS Dropout: High-school dropout; HS: High school diploma (or equivalent); Some college; CC degree Community or junior college degree; BA degree: BA degree; MA degree: postgraduate degree.

$\dots \leq v_7$. The assignment of scores requires some judgment. If one has no particular preference, even spacing allows for the simplest interpretation. The model then becomes

$$\log \mu_{ij} = \mu + \text{PID}_i + \text{Education}_j + \gamma u_i v_j$$

where γ represents the amount of association and is like an (unscaled) correlation coefficient: $\gamma = 0$ means independence. We assigned the scores 1–7 respectively to each of the factors and fit this model. We obtained $\gamma = 0.0287$; the positive value indicates a positive association, although the size of the effect cannot be directly interpreted. The residual deviance is 30.6 which represents a difference of 10.1 for one extra parameter (i.e., on one degree of freedom) from the independence model. This is a strongly significant result, indicating an association here. Notice that it was essential to use the information about the ordinality of the factors to obtain this result.

Summary

Generalized linear models provide a common approach to a broad range of response modeling problems. Normal, Poisson, and binomial responses are the most commonly used, but other distributions can be used as well. GLMs also need a link function to be specified which allows further flexibility in the modeling. The GLM can be fitted using a common procedure and a mechanism for hypothesis testing is available. Diagnostics using residuals provide a way to check that chosen models are adequate.

Even though GLMs have commonalities, GLMs have aspects particular to the response type. For example, a logistic regression is a GLM but the user still needs to understand the particular interpretation of odds in this type of model. With categorical data, the imposition of a GLM sometimes requires parametrizations that are difficult to interpret and other approaches may be more revealing. Thus while GLMs might provide some convenient structure across seemingly different models, we must recognize that they do not provide a comprehensive solution.

The basic GLM has been extended in many directions. [Wedderburn \(1974\)](#) introduced the idea of quasi-likelihood, which avoids explicitly specifying the distribution of the response, requiring only that we specify the link and variance functions. This idea was extended to the notion of generalized estimating equations with particular application to longitudinal data by [Liang and Zeger \(1986\)](#). [Fahrmeir and Tutz \(2001\)](#) describe GLMs for multivariate responses, and random effects can be added to the model using generalized linear *mixed* models ([Stroup, 2012](#)).

Further reading about GLMs can be found in several books. [McCullagh and Nelder \(1989\)](#) is the classical reference although this can be difficult for readers without a background in statistical theory. More accessible texts include [Fox \(2008\)](#) and [Dobson and Barnett \(2008\)](#). [Dunn and Smyth \(2018\)](#) discuss theory, and then explain the application of specific GLMs using R software. [Faraway \(2016\)](#) has an excellent, short introduction to GLMs and extensions based on using R, while [Hardin and Hilbe \(2007\)](#) discuss fitting GLMs in Stata.

Introduction

This article is about techniques for reduction of the data dimensionality. Arguably, the most popular of them is the principal component analysis (PCA) (Jolliffe, 2002). It is used practically in any research field, sometime under different names. Other techniques to be considered here are exploratory factor analysis (EFA) and linear discriminant analysis (LDA). We will see later that both, EFA and LDA, elaborate PCA in some way. For this reason, PCA will be given more attention.

To really appreciate the dimensionality-reduction techniques, it is essential to speak in terms of matrices. So we start with some matrix refreshment.

Matrices and matrix notations

Data matrices

Great number of applications require collecting data arranged in a table, called data matrix. What happens is that for a given set of p variables, measurements are available/made for every involved subject on each variable. The resulting p values are ordered in a p -dimensional vector usually called (multivariate) observation. Further, the already available/made observations are arranged one under another in a table X called a (data) matrix. Suppose that $n(>p)$ observations are available/made altogether. Then the matrix X contains exactly np values: n observations consisting of p values each. We say that the matrix X has size $n \times p$, and assuming that the data are real numbers we write $X \in \mathbb{R}^{n \times p}$. This shows that the matrix X can be considered as either a collection of n row-vectors $(x_i, i = 1, \dots, n)$, called observations, or by p column-vectors $(x_j, j = 1, \dots, p)$, called variables, i.e., $X = [x_1, \dots, x_p]$. We also say that the (data) matrix X has n rows and p columns. Occasionally, the n observations are written as column-vectors of size $p \times 1$ and arranged one to another, resulting in a matrix with n columns and p rows. This is in fact, the transposed matrix to the constructed above X , and is denoted by X^T , i.e. $X^T = [x_1^T, \dots, x_n^T] \in \mathbb{R}^{p \times n}$. For example:

$$A = \begin{bmatrix} 1 & 2 \\ 3 & 4 \\ 5 & 6 \end{bmatrix} \in \mathbb{R}^{3 \times 2} \text{ and } A^T = \begin{bmatrix} 1 & 3 & 5 \\ 2 & 4 & 6 \end{bmatrix} \in \mathbb{R}^{2 \times 3}.$$

Consider the 9×7 data matrix in Table 1, which is a subset of the 24 Psychological Tests given to 145 students in the Grant high school in Chicago (Harman, 1976, p. 123) and (Holzinger and Swineford, 1939). The full data matrix itself is available from the R package MBESS and is obtained by typing data (HS). For simplicity, we consider only six tests, namely Word Recognition (V14), Number Recognition (V15), Figure Recognition (V16), Object-Number (V17), Number-Figure (V18) and Figure-Word (V19) given to the first 9 students, with "M" for male and "F" for female:

Even for this very small data matrix, it is difficult to say much about the involved variables and/or observations (students). Indeed, they can be considered as points in $\mathbb{R}^9$ and $\mathbb{R}^7$ respectively, and thus, difficult to visualize. Unfortunately, this is always the case in real applications, because as a rule the dimension p is much greater than 2 or 3.

Table 1 A subset of 24 psychological tests (Harman, 1976, p. 123).

#	Sex	V14	V15	V16	V17	V18	V19
1	M	173	91	96	8	2	10
2	F	174	81	106	9	15	17
3	M	168	84	101	1	7	16
4	M	130	84	101	10	15	14
5	M	184	98	99	9	9	15
6	F	188	86	116	10	10	16
7	F	192	95	118	16	19	20
8	F	168	97	113	5	6	16
9	F	168	84	107	6	4	7
Mean		171.67	88.89	106.33	8.22	9.67	14.56
Var		327.0	41.6	61.5	16.9	32.0	15.0

That is why, one of the most important tasks in data analysis is the reduction of the data dimensionality p . The rationale behind doing this is twofold: first, not all of the involved variables are equally important, and second, some weighted sum (linear combination) of them can be more informative than each of the individual variables. The purpose of the dimension reduction techniques is to find solutions involving as fewer of the original variables as possible while preserving and explaining as much of the information carried out by the data as possible.

Data matrix pre-processing

For now, let us forget about the categorical variable “Sex” in [Table 1](#), and concentrate on the remaining continuous variables V14 to V19. We note that V14 has much bigger mean and variance than the rest of them. Usually this is caused by measuring the variables in different units, suggesting that they are not readily comparable. The remedy for this is to standardize them, so that they all have zero mean and unit variance. This is achieved by subtracting the mean of each variable/column from its observed values, and then dividing them to the square root of the variance. For example, the value 173 from [Table 1](#) for the first student on V14 is standardized as:

$$\frac{173 - 171.67}{\sqrt{327.0}} = 0.07354917.$$

The easiest way to standardize all variables V14 to V19 from [Table 1](#), is to insert them into an 9×6 matrix, say, X , and use the following R function:

```
scale(X, center = TRUE, scale = TRUE).
```

The resulting standardized variables are given in [Table 2](#):

If the standardized variables from [Table 2](#) are collected in a matrix Z , then the sample correlation matrix of the data is given by

$$\frac{Z^T Z}{n-1}.$$

Nowadays, it is widely accepted first to center the data matrix X , e.g., using R this can be done with:

```
X0 <- scale(X, center = TRUE, scale = FALSE),
```

Table 2 Standardized variables V14 to V19 from [Table 1](#).

#	V14	V15	V16	V17	V18	V19
1	0.07	0.33	-1.32	-0.05	-1.36	-1.18
2	0.13	-1.22	-0.04	0.19	0.94	0.63
3	-0.20	-0.76	-0.68	-1.75	-0.47	0.37
4	-2.30	-0.76	-0.68	0.43	0.94	-0.14
5	0.68	1.41	-0.94	0.19	-0.12	0.11
6	0.90	-0.45	1.23	0.43	0.06	0.37
7	1.12	0.95	1.49	1.89	1.65	1.40
8	-0.20	1.26	0.85	-0.78	-0.65	0.37
9	-0.20	-0.76	0.09	-0.54	-1.00	-1.95
Mean	0	0	0	0	0	0
Var	1	1	1	1	1	1

and then, make its columns/variables have unit lengths (sum of squares):

$$X \leftarrow X0 \% \% \text{diag}(1/\text{sqrt}(\text{colSums}(X0 * X0))).$$

Such pre-processing is known as the data matrix sphering. For sphered X , the product $X^T X$ gives the sample correlation matrix of the data. In other words, the sphered data are obtained from the standardized ones after division by $\sqrt{n-1}$, i.e., $X = Z/\sqrt{n-1}$.

Matrix definitions and operations

The following facts about matrices will be useful in the sequel:

- $A \in \mathbb{R}^{n \times n}$ is called symmetric matrix, if $A = A^T$;
- $D \in \mathbb{R}^{n \times n}$ is diagonal, if its off-diagonal entries are 0 and is denoted by $D = \text{diag}(d_1, \dots, d_n)$; the identity matrix is $I_n = \text{diag}(1, \dots, 1) \in \mathbb{R}^{n \times n}$;
- for $A, B \in \mathbb{R}^{n \times p}$ and $\alpha, \beta \in \mathbb{R}$, we define $\alpha A \pm \beta B = C \in \mathbb{R}^{n \times p}$, and the elements of C are $c_{ij} = \alpha a_{ij} \pm \beta b_{ij}$, where $i = 1, \dots, n, j = 1, \dots, p$;
- for $A \in \mathbb{R}^{m \times n}$ and $B \in \mathbb{R}^{n \times p}$, $AB = C \in \mathbb{R}^{m \times p}$, and the elements of C are $c_{ij} = \sum_{k=1}^n a_{ik} b_{kj}$, where $i = 1, \dots, m, j = 1, \dots, p$; note, that the matrix product is not commutative ($AB \neq BA$)! Indeed:

$$A^T A = \begin{bmatrix} 1 & 3 & 5 \\ 2 & 4 & 6 \end{bmatrix} \begin{bmatrix} 1 & 2 \\ 3 & 4 \\ 5 & 6 \end{bmatrix} = \begin{bmatrix} 35 & 44 \\ 44 & 56 \end{bmatrix} \in \mathbb{R}^{2 \times 2},$$

but

$$AA^T = \begin{bmatrix} 1 & 2 \\ 3 & 4 \\ 5 & 6 \end{bmatrix} \begin{bmatrix} 1 & 3 & 5 \\ 2 & 4 & 6 \end{bmatrix} = \begin{bmatrix} 5 & 11 & 17 \\ 11 & 25 & 39 \\ 17 & 39 & 61 \end{bmatrix} \in \mathbb{R}^{3 \times 3}.$$

- $A \in \mathbb{R}^{p \times p}$ is invertible, if there exists $W \in \mathbb{R}^{p \times p}$, such that $AW = WA = I_p$; then W is called the inverse of A and is denoted by A^{-1} ;
- $A \in \mathbb{R}^{p \times p}$ is singular, if it is not invertible; $A \in \mathbb{R}^{p \times p}$ is singular, if and only if its determinant is 0, and we write $\det(A) = 0$.

Matrix rank and matrix decompositions

The rank of a matrix $A \in \mathbb{R}^{n \times p}$ is a kind of its intrinsic dimension. It is defined as the size of its largest invertible (square) sub-matrix. Let $n > p$, then $A \in \mathbb{R}^{n \times p}$ can have rank at most p . If A does have rank p , it is called full rank matrix. If its rank is $r < p$, then A is called rank deficient. In particular, a square $A \in \mathbb{R}^{p \times p}$ is full rank if and only if it is invertible.

By definition, A and A^T have same ranks. Later we will see how to find the rank of a matrix, as well as that $\text{rank}(A) = \text{rank}(A^T A) = \text{rank}(AA^T)$. These identities imply that if $A \in \mathbb{R}^{n \times p}$ is full rank, so is $A^T A$, and AA^T is rank deficient.

The following useful inequalities hold for any $A \in \mathbb{R}^{n \times p}$ and $B \in \mathbb{R}^{p \times q}$:

$$\text{rank}(A) + \text{rank}(B) - p \leq \text{rank}(AB) \leq \min\{\text{rank}(A), \text{rank}(B)\}. \quad (1)$$

The concept of matrix rank plays a central role in the dimension reduction. To see this, look at the product AA^T from the example above: it demonstrates that a symmetric matrix $S (= AA^T)$ can be represented by a matrix A of a smaller size. In real applications, the dimension reduction task requires solution of the opposite problem: we are given S , and need to find suitable A of a smaller size and/or rank, such that $S = AA^T$ or at least $S \approx AA^T$. The former problem gives an idea of what is meant by matrix decomposition, while the latter one suggests the purpose of the low-rank matrix approximation which aims precisely at dimensionality reduction.

PCA

PCA of correlation matrix (EVD)

PCA is one of the first dimension reduction techniques, introduced by Hotelling (1933) and published (note!) in Journal of Educational Psychology. In fact, Hotelling re-invented the eigenvalue decomposition (EVD) as a tool to find successive and mutually orthogonal principal components (PCs). Later it was realized that the Hotelling's first PC, coincides with the Pearson's (straight) line passing through a cloud of points and minimizing the sum of squared distances between the data points and the line (Pearson, 1901).

EVD states that every symmetric matrix $S \in \mathbb{R}^{p \times p}$ can be written as $S = Q\Lambda Q^T$, where $Q \in \mathbb{R}^{p \times p}$ is orthogonal matrix, i.e., $Q^T Q = QQ^T = I_p$ (identity matrix), and $\Lambda = \text{diag}(\lambda_1, \dots, \lambda_p) \in \mathbb{R}^{p \times p}$ is diagonal matrix, with $\lambda_1 \geq \dots \geq \lambda_p$. If all $\lambda_i > (\geq) 0$, then S is called

positive (semi-)definite. The columns of $Q (= [q_1, \dots, q_p])$ are called eigenvectors of S and λ_i is the eigenvalue corresponding to q_i . If all λ_i are different, then Q is unique. Note that $\det(S) = \lambda_1 \dots \lambda_p > 0$, i.e., a positive definite S is always invertible.

Suppose $X \in \mathbb{R}^{n \times p}$ is a full rank sphered data matrix. Then, its sample correlation matrix $X^\top X$ is a positive definite matrix with unit main diagonal. This assumption is not too restrictive, because most real data need standardization of the original variables. Then, applying EVD to $X^\top X$ gives:

$$X^\top X = Q\Lambda Q^\top = \lambda_1 q_1 q_1^\top + \dots + \lambda_p q_p q_p^\top, \quad (2)$$

where $\lambda_1 \geq \dots \geq \lambda_p > 0$. Very small eigenvalues of $X^\top X$ usually indicate data problems, e.g., some variable (column of X) is a multiple of another one, known as collinearity.

Let us see now, how the neat mathematical representation (2) of $X^\top X$ translates into statistical terms. First, the elements of the eigenvectors q_i of $X^\top X$ are called component loadings. Multiplying (2) on the left hand side by $q_1^\top$ and on the right hand side by q_1 gives:

$$q_1^\top X^\top X q_1 = (X q_1)^\top X q_1 = y_1^\top y_1 = \lambda_1. \quad (3)$$

The linear combination $y_1 = X q_1$ is called the first PC. As X is centered (as sphered), y_1 is centered too. This shows that the variance of y_1 is simply given by the sum of its squared elements and thus, equal to the corresponding eigenvalue λ_1 . More generally, the variances of the PCs are given by the eigenvalues of $X^\top X$, which explains, why they cannot be negative.

Consider the transformed data matrix $Y = XQ \in \mathbb{R}^{n \times p}$, known as the matrix of component scores. As Q is orthogonal matrix, this implies that Y is obtained from X by a high-dimensional orthogonal rotation, which by definition preserves angles and lengths. In this connection it is worth reminding that the oldest approach to EVD proposed by [Jacobi \(1846\)](#) relies on successive planar rotations. As X is centered, so is Y . It follows from (3), that the covariance matrix $Y^\top Y$ of the PCs, is diagonal Λ .

The sum of the diagonal elements of a square matrix $A \in \mathbb{R}^{p \times p}$ is called trace and it is denoted by $\text{trace}(A)$. Direct calculations show that $\text{trace}(AB) = \text{trace}(BA)$ for any two matrices $A, B \in \mathbb{R}^{n \times p}$. The total variance contained in the data X is given by the sum of the variances of all variables, i.e., by the trace of the covariance matrix. In our situation, the covariance matrix reduces to the sample correlation matrix $X^\top X$, which trace is p : the sum of its unit diagonal entries. Then, it follows from (2) that:

$$\text{trace}(X^\top X) = \text{trace}(Q\Lambda Q^\top) = \text{trace}(Q^\top Q\Lambda) = \text{trace}(\Lambda) = \sum_{i=1}^p \lambda_i = p,$$

This shows that the PCs in Y have the same total variance as the original variables, $\text{trace}(Y^\top Y) = \text{trace}(\Lambda)$, and that the average PC variance is 1.

The expression (2) immediately appeals for dimension reduction: we can choose any number $r < p$ to approximate $X^\top X$ as follows:

$$X^\top X \approx \lambda_1 q_1 q_1^\top + \dots + \lambda_r q_r q_r^\top, \quad (4)$$

where the right hand side of (4) is a sum of matrices of rank 1 each, as products of vectors. Moreover, $\text{trace}(X^\top X) = p \approx \lambda_1 + \dots + \lambda_r$, which helps to measure how good our approximation is. It is common practice to take into account only the eigenvalues with values greater than average, i.e., $\lambda_i > 1$, and use their eigenvectors in (4) for low-rank approximation of $X^\top X$.

It is convenient to have (4) expressed in matrix form as follows:

$$X^\top X \approx Q_r \Lambda_r Q_r^\top = (Q_r \Lambda_r^{1/2}) (Q_r \Lambda_r^{1/2})^\top, \quad (5)$$

where $\Lambda_r = \text{diag}(\lambda_1, \dots, \lambda_r) \in \mathbb{R}^{r \times r}$ is diagonal matrix containing the first largest r eigenvalues of $X^\top X$, and $Q_r = [q_1, \dots, q_r] \in \mathbb{R}^{n \times r}$ is composed by the first r columns of Q (corresponding eigenvectors). A matrix that contains a subset of the columns of an orthogonal matrix is called orthonormal, i.e., Q_r is orthonormal and $Q_r^\top Q_r = I_r$ only.

Let us apply what we know so far on the small data set in [Table 1](#), or more precisely to the sphered variables V14 to V19. Their sample correlation matrix is given by:

$$X^\top X = \begin{bmatrix} 1.00 & 0.41 & 0.45 & 0.29 & 0.01 & 0.32 \\ 0.41 & 1.00 & 0.15 & 0.26 & -0.08 & 0.24 \\ 0.45 & 0.15 & 1.00 & 0.43 & 0.43 & 0.49 \\ 0.29 & 0.26 & 0.43 & 1.00 & 0.71 & 0.38 \\ 0.01 & -0.08 & 0.43 & 0.71 & 1.00 & 0.74 \\ 0.32 & 0.24 & 0.49 & 0.38 & 0.74 & 1.00 \end{bmatrix}.$$

If we insert this correlation matrix into an R data frame and apply `eigen()`, we find that its eigenvalues are: 2.84, 1.37, 0.74, 0.61, 0.41 and 0.03. Only the first two are greater than the average PC variance 1, which suggests to use the first two PCs, and produce

Fig. 1 Scree plot (left panel) and component loadings plot.

a rank-2 approximation to $X^T X$. They explain 70.08% $\left(= \frac{2.8395+1.3654}{6}\right)$ of the total variance, and as a result, we are able to analyze the data using only two PCs, rather than the initial six variables, i.e. we achieve two-thirds dimension reduction. With this PCA solution we achieve a rank-2 approximation of $X^T X$, namely $X^T X \approx \lambda_1 q_1 q_1^T + \lambda_2 q_2 q_2^T = Q_2 \begin{bmatrix} \lambda_1 & 0 \\ 0 & \lambda_2 \end{bmatrix} Q_2^T$.

In this case, the decision for the number of useful PCs is easy, because their variances are well away from 1. In practice, it is common to draw a scree plot of the variances as in **Fig. 1**(left), and consider only the PCs before the graph flattens. Following this rule, one can conclude that, in fact, three PCs are the best choice. Indeed, they explain 82.46% $\left(= \frac{2.8395+1.3654+0.7427}{6}\right)$, which brings considerable improvement in the fit, but the level of dimension reduction is compromised: we need three PCs, which is half the number of the original variables. This situation gives a flavor of the inevitable bargaining of fit for simplicity and vice versa accompanying the dimension reduction.

Suppose, we make our choice in favor of the simplicity and work only with the first two PCs. Their component loadings are given in the left two columns of **Table 3**. Clearly, the first PC represents the relative weights of the involved six variables, while the second PC separates the “recognition” variables (V14, V15 and V16) from the “comparative” ones (V17, V18 and V19). Their graphical representation in **Fig. 1**(right) is quite interesting. It reveals that V16 is, in fact, closer to the “comparative” tests. Moreover, if the coordinate system is rotated such that the first axis follows the direction of the dashed line, then the separation of the two groups of tests can be achieved in a single dimension. Note, that many statistical packages report the PC loadings as they are given in the right couple of columns of **Table 3**.

PCA of data matrix (SVD)

Nearly at the same time when Hotelling proposed his PCA with EVD of covariance/correlation matrix, another matrix decomposition was proposed by [Eckart and Young \(1936\)](#). This is the singular value decomposition (SVD) and its great importance is that PCA can be performed directly on the data matrix X . Any potential noise and/or errors in the data multiply when forming the covariance/correlation matrix. Thus, working with SVD is beneficial in two ways: saves calculations and offers more precise analysis.

To simplify the notations, we consider the so-called economy SVD, which states that for every matrix $X \in \mathbb{R}^{n \times p}$, there exists orthonormal matrix $U \in \mathbb{R}^{n \times p}$ ($U^T U = I_p$) and orthogonal matrix $V \in \mathbb{R}^{p \times p}$, such that:

$$X = U \Sigma V^T = \sigma_1 u_1 v_1^T + \dots + \sigma_p u_p v_p^T, \quad (6)$$

Table 3 Two ways to report component loadings.

	q_1	q_2	$q_1 \sqrt{\lambda_1}$	$q_2 \sqrt{\lambda_2}$
V14	0.31	−0.57	0.53	−0.67
V15	0.21	−0.62	0.36	−0.73
V16	0.44	−0.07	0.74	−0.08
V17	0.46	0.12	0.78	0.14
V18	0.47	0.50	0.79	0.58
V19	0.48	0.12	0.82	0.14
SS	1	1	2.84	1.37

where $\Sigma = \text{diag}(\sigma_1, \dots, \sigma_p) \in \mathbb{R}^{p \times p}$ with $\sigma_1 \geq \dots \geq \sigma_p \geq 0$, called singular values of X . The number of positive singular values of X gives its rank.

A left multiplication of (6) by $X^\top$ gives $X^\top X = V\Sigma^2 V^\top$, which connects the SVD of X to the EVD of $X^\top X$ by taking $Q = V$ and $\lambda_i = \sigma_i^2, i = 1, \dots, p$ in (2). Similarly, a right multiplication of (6) by $X^\top$ shows that the columns of U are eigenvectors of $XX^\top$, and $\sigma_1^2, \dots, \sigma_p^2$ are also their eigenvalues. Thus, $X^\top X$ and $XX^\top$ have the same (non-zero) eigenvalues, and same ranks.

As with (2) for the EVD case, we can achieve dimension reduction with (6), by choosing any number $r < p$ and approximate X as follows:

$$X \approx \sigma_1 u_1 v_1^\top + \dots + \sigma_r u_r v_r^\top, \quad (7)$$

where the right hand side of (7) is again a sum of matrices of rank 1 each. Here, we measure the goodness of our approximation by $\text{trace}(X^\top X) = p \approx \sigma_1^2 + \dots + \sigma_r^2$.

It is convenient to have (7) expressed in matrix form as follows:

$$X \approx U_r \Sigma_r V_r^\top, \quad (8)$$

where $\Sigma_r = \text{diag}(\sigma_1, \dots, \sigma_r) \in \mathbb{R}^{r \times r}$ contains the first largest r singular values of X , with the corresponding columns (singular vectors) in U_r and V_r .

The matrix of component scores $Y = XQ = XV$ from Section **PCA of correlation matrix (EVD)** is also given by $Y = U\Sigma$ from (6). Going back to the data set in **Table 2**, we realize that PCA can be performed without forming $X^\top X$. By applying the R function `svd()` to X , we find the component loadings matrix V , which coincides with Q from (2). The right number of components to use is found in the same way as in **PCA of correlation matrix (EVD)** section.

Finally, note that some people use $V\Sigma$ and U for loadings and scores instead. For example, this is the case with SPSS. Of course, this is just a matter of scaling and does not affect the interpretation. One can easily recognize which scaling is used by adding the squared loadings. If they add up to 1, then V is the loadings matrix. If they add up to the variance of the corresponding component, $V\Sigma$ present the loadings.

Our personal opinion is that loadings with unit lengths are easier to interpret within a component, and to compare between components. Thus, if the loadings are of interest, we would take V and the scores become $U\Sigma$. However, if the scores are of interest, we would work with (orthonormal) U and the loadings become $V\Sigma$.

EFA

EFA is another dimension reduction technique, which model is much more complicated than PCA. As a result EFA needs whole books to cover different aspects and approaches ([Bartholomew et al., 2011](#)). Applying EFA is also more complicated. The simplest option seems to be the R function `factanal`; for more complex EFA needs there are R libraries like `psych` or `fungible`.

Not surprisingly, all these features make EFA far less popular than PCA. To simplify our task we concentrate on the dimension reduction aspect of EFA and view it as another (data) matrix decomposition ([Harman, 1976](#)).

Let $X \in \mathbb{R}^{n \times p}$ be a standardized data matrix. The EFA model is in fact a specific matrix decomposition/factorization of X ([Harman, 1976, 2.9](#)):

$$X \approx FL^\top + P\Psi, \quad (9)$$

where the matrix parameters $F \in \mathbb{R}^{n \times r}$, $L \in \mathbb{R}^{p \times r}$, $P \in \mathbb{R}^{n \times p}$ and $\Psi \in \mathbb{R}^{p \times p}$ (diagonal) are unknown. Note that, as X is centered, so are F and P .

It is very helpful to rewrite (9) using block matrices as follows:

$$X \approx FL^\top + P\Psi = [F \ P][L \ \Psi]^\top = WA^\top, \quad (10)$$

where $W = [F \ P] \in \mathbb{R}^{n \times (r+p)}$ means that F and P are put next to each other and form a “bigger” matrix W with the same number of rows, but with $r + p$ columns. As seen from (10), the blocks are treated as single entries in matrix manipulations, i.e., $W = [F \ P]$ and $A = [L \ \Psi]$ are treated as 1×2 vectors.

The product $FL^\top$ in (9) provides the (low) rank- r approximation of X , while each column of $P\Psi$ only adjusts the corresponding column in $FL^\top$. That is why F and P are called respectively common and specific/unique factors. Clearly, their roles are very different and they need to be well separated. For this reason, the EFA model (9) requires F and P to be uncorrelated/orthogonal to each other: $F^\top F = I_r, P^\top P = I_p, F^\top P = O_{r \times p}$. Equivalently, the block matrices in (10) fulfill $W^\top W = I_{(r+p)}$.

The classical EFA makes use of (10) to derive:

$$X^\top X \approx (WA^\top)^\top (WA^\top) = AA^\top = LL^\top + \Psi^2, \quad (11)$$

which, in turn is an EFA model for the sample correlation matrix $X^\top X$. The model (11) has only two unknowns L and Ψ . The term $LL^\top$ is a (low) rank- r approximation to the covariances (off-diagonal elements) of $X^\top X$, while Ψ^2 simply adjusts its diagonal entries

to fit the main (unit) diagonal of $X^\top X$. As Ψ^2 is sparse (contains only $1/p$ non-zero entries), this makes the EFA model (11) the oldest matrix completion problem.

Comparing (5) and (11) clearly shows the difference between PCA and EFA: PCA finds the best low rank r approximation to $X^\top X$, while EFA finds the best low rank r approximation to the covariances of $X^\top X$. Note, that in general the approximation $LL^\top + \Psi^2$ to $X^\top X$ is not a low rank matrix.

The considerable difference between the EFA model (10) and SVD is in the specific structure of $A (= [L \ \Psi])$. As a result, W and A cannot be found such that the model fits X exactly. Instead, F, L, P and Ψ are sought such that the difference/error $E = X - WA^\top$ is made as small as possible. Here we want to make the sum of squared errors $\sum_i \sum_j e_{ij}^2 = \text{trace}(E^\top E)$ as small as possible, which is known as the least-squares EFA (LS-EFA).

First, making use of $W^\top W = I_{(r+p)}$, we find that the sum of squares is:

$$\text{trace}(E^\top E) = \text{trace}(X^\top X) - 2\text{trace}(W^\top XA) + \text{trace}(A^\top A), \quad (12)$$

and note that the first term in (12) is constant. Second, we observe that the last term in (12) depends on A only. This suggests a simple alternating procedure to find W and A . First, fix $A = [L \ \Psi]$, and solve:

$$\max_W \text{trace}(W^\top XA), \quad (13)$$

for $W = [F \ P]$. To do this, consider the SVD of $XA = U\Sigma V^\top$, which suggests that the solution of (13) is $W = UV^\top$. Second, update $A = [L \ \Psi] = [X^\top F \text{diag}(X^\top P)]$. Plug the new A back in (13) and repeat the process until, say, $\text{trace}(E^\top E) < 10^{-6}$. This can be implemented in a small R code.

Unfortunately, this solution is not unique, because $XA \in \mathbb{R}^{n \times (r+p)}$ is always rank deficient. This conclusion follows from (1), by noting that X and A have ranks at most p . This lack of uniqueness is the notorious factor indeterminacy in EFA.

We apply the proposed alternating EFA procedure to the small data from **Table 1**. Again, we work with the sphered data matrix X already subject to PCA in **PCA of correlation matrix (EVD)** section. We look for two-factor ($r = 2$) solution, to keep the results comparable to the PCA ones. We also apply another LS-EFA procedure fals from the R library fungible, which finds L_R and Ψ_R by LS minimization of the difference/error $E = X^\top X - LL^\top - \Psi^2$ in (11).

The results are summarized in **Table 4**. The unique variances in Ψ_R^2 and Ψ^2 are reasonably similar, except the entry for V14. At first glance, the factor loadings L_R and L seem quite different. However, their plots in **Fig. 2** show that they form very similar configurations of points in $\mathbb{R}^2$, possibly after some reflection.

The last couple of columns of **Table 4** show that L matches L_R very well after multiplication by the orthogonal $Q_R = \begin{bmatrix} 0.5427 & -0.8400 \\ -0.8400 & -0.5427 \end{bmatrix}$. One notes that $\det(Q_R) = -1$, i.e., indeed, Q_R is a reflection, which makes an angle -28.57° with the first axis $e_1 = (1, 0)$. Both factor loadings L and L_R testify for distinction of V14, V15 from V16, and for their separation from V17, V18 and V19. This separation is also clearly visible in **Fig. 2**, as well as that it can be realized in a single dimension. Variables like V18 with zero unique variance are considered singular and are known as Heywood cases. Note, that many EFA numerical procedures, e.g., fals, keep such variances at 0.005.

The component loadings from the last two columns of **Table 3** (given by $V\Sigma$ from (6)) can be roughly compared to the factor loadings in **Table 4**. Their values are reasonably similar to the factor loadings L_R . Their plots depicted respectively in **Fig. 1** and **Fig. 2**, also support such a conclusion.

It is interesting to visualize the students as presented by the component and factor scores. As $F^\top F = I_r$, we take U from (6) as component scores for this comparison. Indeed, we also have for them $U^\top U = I_r$, and the scaling with Σ is already applied above to the loadings $V\Sigma$. **Fig. 3** shows that the male and female students are not separated.

LDA

LDA is designed to analyze data with observations divided into, say, g groups, i.e., the rows of X are grouped. We will see that LDA achieves dimensionality reduction, which is additionally facilitated by the presence of groups.

As with PCA, LDA considers linear combinations $Y = XA$ of the original variables, usually called canonical variates (CVs), or discriminant functions. The LDA goal is to find a full-rank matrix $A \in \mathbb{R}^{p \times r}$, such that the groups are better separated/discriminated in the transformed data $Y (=XA)$, than with respect to any of the original variables. The number r of “new” variables (CVs) is usually much smaller than p . In fact, it should be $r < \min\{p, g\}$. In this sense, LDA is another dimension reduction technique.

As before, n observations are made on p variables which are collected in a $n \times p$ ($n > p$) data matrix X . The difference is that these n observations are a priori divided into g groups/populations. Thus, if n_i is the number of individuals in the i th group, then we have $n_1 + n_2 + \dots + n_g = n$. For example, as indicated by the variable Sex in Table 1, we have male and female students, i.e., the observations of these data are divided into two groups, $g = 2$.

The observations group membership is expressed by an indicator matrix $G \in \mathbb{R}^{n \times g}$ of zeros and ones. Each column of G corresponds to one group and has 1 at its i th position if the i th observation of X belongs to that particular group and zero otherwise. Clearly, we have $G^T G = \text{diag}(n_1, \dots, n_g) = N$. The matrix containing the means of the groups is given by $\bar{X} = N^{-1} G^T X$.

For example, here is the group indicator matrix G for the data in Table 1:

$$\text{Sex} = (\text{M F M M M F F F})^T \Rightarrow G = \begin{bmatrix} 0 & 1 & 0 & 0 & 0 & 1 & 1 & 1 & 1 \\ 1 & 0 & 1 & 1 & 1 & 0 & 0 & 0 & 0 \end{bmatrix}^T,$$

and respectively $G^T G = \begin{bmatrix} 5 & 0 \\ 0 & 4 \end{bmatrix} = N$ and $\bar{X} = N^{-1} G^T X$ gives:

$$\bar{X} = \begin{bmatrix} 0.12 & -0.02 & 0.26 & 0.08 & 0.07 & 0.06 \\ -0.15 & 0.02 & -0.32 & -0.11 & -0.09 & -0.07 \end{bmatrix}.$$

Let X be centered/sphered data matrix. In LDA, the sample covariance/correlation matrix $X^T X$ is usually denoted by S_T (for Total). The following representation of S_T plays a central role in LDA:

$$\begin{aligned} S_T &= X^T X + \bar{X}^T N \bar{X} - \bar{X}^T N \bar{X} = (G\bar{X})^T (G\bar{X}) + (X - G\bar{X})^T (X - G\bar{X}) \\ &= X_B^T X_B + X_W^T X_W = S_B + S_W, \end{aligned} \quad (14)$$

Fig. 4 Discriminant function (CV) and scores.

where S_B and S_W express the between- and within-groups scatter/variability of the data. There are two important implications following from (14):

1. S_B is a product of G and $\bar{X}$ with ranks $\min\{n, g\}$ and $\min\{p, g-1\}$ respectively; then, it follows from (1) that its rank can be at most $\min\{p, g-1\}$;
2. S_T is given/fixed, so the separation among the groups can be improved, either by “increasing” S_B , or by “reducing” S_W (Fisher, 1936).

The latter observation helps to define LDA as the following problem:

$$\max_a \frac{a^\top S_B a}{a^\top S_T a}, \quad (15)$$

which is solved in turn for every column of the transformation $A = [a_1, \dots, a_r]$.

The LDA problem (15) is equivalent to the following generalized EVD:

$$(S_B - \mu S_T)a = 0_p, \quad (16)$$

and can be solved by the function `geigen` from the R package `geigen`.

For our example with $g = 2$, LDA can produce only one CV. Thus, the dimension is reduced to $r = 1$, and $A \equiv a \in \mathbb{R}^p$. Indeed, the solution of (16) gives a single non-zero eigenvalue $\mu = 0.8487$ with corresponding eigenvector:

$$a = (-0.2820, 0.0822, -1.0398, 0.2788, -0.4286, 0.5809) \in \mathbb{R}^6,$$

satisfying $a^\top S_T a (= a^\top X^\top X a) = 1$. The coefficients of (the CV) a order the variables on the line as seen in Fig. 4: V16, V18, V14, V15, V17, V19. This is quite a different interpretation from the one of PCA, which orders them as V15, V14, V16, V17, V19, V18 on the hypothetical dashed line in Fig. 1.

Finally, the one-dimensional LDA projection $y = Xa$ ($y^\top y = 1$) of the students is given by their discriminant scores:

$$y = (0.45, -0.03, 0.22, 0.33, 0.38, -0.45, -0.41, -0.16, -0.33) \in \mathbb{R}^9,$$

where, since students 2, 6, 7, 8, and 9 are female, the male and female students are clearly separated with their positive and negative scores. This outperforms the two-dimensional plots of the component and factor scores depicted in Fig. 3. This is not surprising, because the LDA primary goal is the separation of the groups of observations. On the other hand, the LDA variables representation in Fig. 4 looks less satisfying than the outcomes from PCA and EFA, depicted in Fig. 2.

As with PCA and EFA, we can do LDA using X and X_B only, without forming S_T and S_B needed for (15) and (16). This is achieved by their generalized SVD and the function `gsvd` from the same package `geigen`. The only non-zero generalized singular values of X_B and X are 0.6776 and 0.7355. Their squared quotient gives the same eigenvalue μ as above. However, the corresponding generalized singular vector b is only proportional to a , obtained from (16), i.e., $b = \alpha a$ for some $\alpha > 0$. The correct CV a is reconstructed by taking $\alpha = \sqrt{b^\top S_T b}$.

Concluding remarks

Nowadays, the methods for dimension reduction routinely analyze huge data sets with thousands or even millions of variables. This requires modifications to drastically reduce their number by dropping off less important variables and produce sparse solutions, involving only fewer important ones. Thus, the goodness-of-fit of the dimension reduction is further compromised and traded for a clearer and/or easier interpretation. This is a very active research area and brings together artificial intelligence, machine learning and statistical communities. Some modern aspects of PCA, EFA and LDA are considered in (Trendafilov and Gallo, 2021).

Introduction

Factor analysis (FA) originated in psychometrics as a tool to model and measure the human abilities and associated individual differences. In 1904, Charles Spearman published his seminal paper (Spearman, 1904), which is considered the beginning of FA. The purpose was to measure the human intelligence, thought at that time to be a single unobservable entity, called general intelligence g . He used regression-like equations but with the difference that g is not available (observable) as in the regression problems. Soon, the theory of intelligence evolved and the Spearman’s (one factor) model with a single latent construct became less popular and replaced by the so called multiple FA (Thurstone, 1947).

There are two major approaches to FA: exploratory (EFA) or confirmatory (CFA) (Mulaik, 2010, Ch 15). Here we concentrate on EFA. Its difference from CFA will be briefly outlined in the next section.

EFA model

Suppose, we are given p centered variables $x_i, i = 1, \dots, p$. EFA models every variable x_i as the following linear combination:

$$x_i \approx \lambda_{i1}f_1 + \dots + \lambda_{ir}f_r + \psi_i u_i = \sum_{j=1}^r \lambda_{ij}f_j + \psi_i u_i, \quad (1)$$

where $f_1, \dots, f_r$ and $u_1, \dots, u_p$ are called respectively common and unique or specific factors. Thus, there are $r(< p)$ common factors for all x_i , and p unique factors, one for each of the input variables, which explains their name.

A graphical expression of the EFA model can be given by a path diagram as depicted in Fig. 1. The variable x_i is affected by the r common factors $f_1, \dots, f_r$ and by the unique factor u_i . We will see later, that the factor loading λ_{ij} gives the correlation between x_i and f_j .

Usually we work with a $n \times p$ ($n > p$) data matrix $X = [x_1, \dots, x_p]$ of n observations made on p standardized variables divided by $\sqrt{n-1}$, i.e. $X^T X$ is their sample correlation matrix. Then the classical EFA model in (1) is more convenient to be rewritten in matrix form as follows (Mulaik, 2010, p. 136):

$$X \approx F\Lambda^T + U\Psi, \quad (2)$$

where the common and unique factors from (1) are collected as columns of the $n \times r$ matrix F and the $n \times p$ matrix U respectively. As X is centered, F and U are centered, i.e. $1_n^T F = 0_r$ and $1_n^T U = 0_p$ (zero vectors). Λ is known as the matrix of factor loadings, while Ψ is diagonal and Ψ^2 gives the variances of the unique factors U . Thus, ψ_i^2 is the part of the variance of the i th variable x_i that the common factors cannot explain.

Eq. (2) is called the r -factor EFA model. The number r of factors is usually much smaller than the number p of input variables and will be discussed in Section Number of factors.

By definition, the unique factors U are uncorrelated and with unit lengths, that is, $U^T U = I_p$, which is to say that U is an orthogonal matrix. Moreover, the common and unique factors are assumed uncorrelated, i.e. $F^T U = 0_{r \times p}$ (zero matrix), meaning they are orthogonal to each other. Then, the EFA model (2) implies the following model for the correlation matrix of the data:

Fig. 1 Path diagram of the EFA model (1) for $p = 5$ and $r = 2$.

$$\begin{aligned} X^T X \approx R_{XX} &= (F\Lambda^T + U\Psi)^T (F\Lambda^T + U\Psi) = \\ &= \Lambda F^T F \Lambda^T + \Lambda F^T U \Psi^T + \Psi U^T F \Lambda^T + \Psi U^T U \Psi = \\ &= \Lambda F^T F \Lambda^T + \Psi^2. \end{aligned} \quad (3)$$

Clearly, $F^T F$ can be seen as the covariance matrix of the common factors. EFA assumes that the common factors F also have unit variances, i.e. have unit lengths, which makes of $F^T F$ the correlation matrix of the common factors. Most frequently, they are considered uncorrelated, i.e. $F^T F = I_r$, and F is an orthonormal matrix. Then, (3) simply reduces to:

$$X^T X \approx R_{XX} = \Lambda \Lambda^T + \Psi^2, \quad (4)$$

well known as the EFA model for the sample correlation matrix. The EFA problem is to find Λ and Ψ such that R_{XX} fits $X^T X$ as close as possible.

The EFA model (4) of the correlation structure of the data clearly shows the EFA idea: $\Lambda \Lambda^T$ fits the off-diagonal elements of $X^T X$, i.e. the sample correlations, while the unique variances Ψ^2 simply adjust the diagonal elements of $\Lambda \Lambda^T$ to fit the unit main diagonal of $X^T X$. This exhibits the different roles of the common and unique factors in EFA, expressed by $F^T U = O_{r \times p}$. We stress that EFA fits the correlations among the p input variables by means of only r factors, which makes it a dimension reduction technique.

Left multiplication of (2) by F^T gives $\Lambda = X^T F$, suggesting that λ_{ij} can be treated as correlation between the i th variable and the j th factor. Then, λ_{ij}^2 is the contribution of the j th factor to the variance of the i th variable.

Now, we can mention briefly the difference between EFA and CFA. In EFA, there are no constraints on the factor loadings Λ . In contrast, CFA may assume/speculate that some λ_{ij} take zero values, and thus impose a priori lack of relationships among certain factors and variables. Thus, EFA and CFA represent different approaches of using the same common-factor model (4). The purpose of CFA is to utilize preliminary knowledge or hypothesis.

It follows from (4), that the diagonal elements of $\Lambda \Lambda^T$ and Ψ^2 should add up to 1, which can be written as:

$$\text{diag}(X^T X) = I_p = \text{diag}(\Lambda \Lambda^T) + \text{diag}(\Psi^2) = \text{diag}(\Lambda \Lambda^T) + \Psi^2,$$

where $\text{diag}()$ makes a diagonal matrix from its argument. The entries of $\text{diag}(\Lambda \Lambda^T) = I_p - \Psi^2$ are called communalities of the original variables. They give the part of the variance of the observed variables due to just common factors. Note, that the entries of $\text{diag}(\Lambda^T \Lambda)$ give the contributions of each common factor to the total variance.

It is worth reminding that the trace of a square $p \times p$ matrix A is the sum of its diagonal elements. It is denoted by $\text{trace}(A)$ and the definition implies that $\text{trace}(A^T) = \text{trace}(A)$ and $\text{trace}(AB) = \text{trace}(BA)$. In particular, $\text{trace}(\Lambda \Lambda^T) = \text{trace}(\Lambda^T \Lambda)$. By taking trace from both sides of (4), we find another useful identity of the EFA model:

$$\text{trace}(X^T X) = p = \text{trace}(\Lambda^T \Lambda) + \text{trace}(\Psi^2),$$

indicating that the total variance of the input variables is composed by the total contribution of the common factors and the variances of the unique factors.

Number of factors

Sometimes, we want a solution with a specific or prescribed number r of factors. Then, we simply look for a r -factor EFA solution. Particularly, the choice of $r = 2$ is very popular because the resulting $p \times 2$ matrix of factor loadings Λ can be plotted on the plane.

However, in general, this is not the case: r is unknown in advance and needs to be found. There exist two very simple and popular heuristic ways to find, or at least to suggest, a suitable number of factors (Mulaik, 2010, 8.2.11). They both use the eigenvalues of the sample correlation matrix $X^T X$. The Kaiser's rule makes r equal to the number of eigenvalues greater than one. The second way is graphical and uses the so-called "elbow" or "scree" plot. The ordered in decreasing order eigenvalues are plotted (against their order) and r is made equal to the number before which the graph flattens.

In reality, their application is not so straightforward as it may look by their simplicity. For example, eigenvalues close to 1 make the Kaiser's rule inconclusive. Similarly, the "elbow" plot may flatten at two or more eigenvalues, or not flatten at all. The standard practice is to try several plausible values of r and compromise between simpler model (smaller r), or better fit of the model to the data.

We can illustrate these potential complications with the small well-known data set of Five Socio-Economic Variables (Harman, 1976, Table 2.1, p. 14). It contains $n = 12$ observations (census tracts of small areal subdivisions of Los Angeles, CA) and $p = 5$ variables, Total Population (POP), Median School Years (SCH), Total Employment (EMP), Misc. Professional Services (SER) and Median Value House (HOU). They are measured in different units and we need to standardize them and analyze their sample correlation matrix:

$$X^T X = \begin{bmatrix} 1.000 & .0098 & .9724 & .4389 & .0224 \\ .0098 & 1.000 & .1543 & .6914 & .8631 \\ .9724 & .1543 & 1.000 & .5147 & .1219 \\ .4389 & .6914 & .5147 & 1.000 & .7777 \\ .0224 & .8631 & .1219 & .7777 & 1.000 \end{bmatrix}. \quad (5)$$

The eigenvalues of $X^T X$ are 2.87, 1.80, 0.21, 0.10 and 0.02. According to the Kaiser's rule we conclude without hesitation that two factors are appropriate for these data. Moreover, they carry 93.4% $\left(= \frac{2.8733+1.7967}{5} \times 100\% \right)$ of the total variance of the data.

Now, let us look at the scree plot of these eigenvalues in Fig. 2. We see with surprise that it clearly suggests using three factors. Apparently, this is not a very good idea: the three eigenvalues explain 97.7% of the total variance, which is only 4% more than the first two, but result in a more complicated EFA model (involving three factors for five original variables).

A likely source for problems with these heuristic methods is that they are based on the eigenvalues of $X^T X$, while the common factors F are responsible for part of it only. Nowadays, the Horn's parallel method is becoming a popular alternative of the elbow/Kaiser's rule. The idea is to compare the available eigenvalues of $X^T X$ to the average eigenvalues of simulated zero-mean uncorrelated multivariate normal data of the same size. The rule is to count only the actual eigenvalues greater than the simulated ones. For our example, we find average simulated eigenvalues to be 1.91, 1.32, 0.92, 0.58 and 0.28, that is, only the first two eigenvalues of $X^T X$ are greater than the simulated ones and thus, $r = 2$. More details on how to evaluate the number r of common factors can be found in (Mulaik, 2010, 8.2.11).

Fig. 2 Scree plot of the sample correlation matrix (5).

Two ways to find Λ and Ψ

In order to evaluate the closeness of R_{XX} to $X^\top X$, we need a discrepancy measure. Probably, the most natural way to approach the problem is to consider their difference $E = X^\top X - R_{XX}$. Then we can find Λ and Ψ such that the sum of squared errors $\sum_{ij}^p e_{ij}^2 = \text{trace}(E^\top E) = \text{trace}(E^2)$ is made as little as possible. This problem is known as the least-squares EFA (LS-EFA) and can be summarized as:

$$\min_{\Lambda, \Psi} \text{trace} \left[\left(X^\top X - \Lambda \Lambda^\top - \Psi^2 \right)^2 \right]. \quad (6)$$

If the standardized data are assumed normally distributed with zero mean and correlation matrix given by R_{XX} as in (4), then the likelihood function for $X^\top X$ can be used as a discrepancy measure. Its minimization with respect to Λ and Ψ gives the following maximum likelihood EFA problem (ML-EFA):

$$\min_{\Lambda, \Psi} \log \left(\det \left(\Lambda \Lambda^\top + \Psi^2 \right) \right) + \text{trace} \left(\left(\Lambda \Lambda^\top + \Psi^2 \right)^{-1} X^\top X \right). \quad (7)$$

It is important to stress that ML-EFA (7) can be used safely with non-normally distributed data (Mulaik, 2010, 8.3.9).

Let us apply LS-EFA and ML-EFA to the sample correlation matrix (5) of the Five Socio-Economic Variables. We solve both EFA problems (6) and (7) by using `fals` and `faml` respectively from the R package `fungible`. The resulting factor loadings Λ and unique variances Ψ^2 are given in Table 1.

The values of Ψ^2 show how well the corresponding variables are fit by the common factors. However, zero unique variances are traditionally considered unrealistic and are referred to as “Heywood cases” (Harman, 1976, 7.3). For this reason, many EFA programs (including `fungible`) do not permit unique variances less than 0.005. This phenomenon is illustrated in the ML-EFA solution in Table 1, where a Heywood case is obtained for POP.

In general, the Heywood cases are considered statistical phenomenon (Bartholomew et al., 2011), which may result from a range of factors: from simple sampling errors to wrong number r of factors. Nowadays many researches relax this restriction and admit zero unique variances.

EFA interpretation

After the EFA solution $\{\Lambda, \Psi\}$ is found by solving LS-EFA (6) or ML-EFA (7), we need to interpret it. This second stage of EFA is very important by itself and is the subject of this Section.

The EFA interpretation is mainly based on the factor loadings Λ . We already know that λ_{ij} is the correlation between the i th input variable and the j th factor. In other words, λ_{ij} expresses the importance of the j th factor in the linear approximation of the i th input variable. In this sense, the factor loadings interpretation will be simplified if their magnitudes are either near zero or near one.

Let us interpret the LS-EFA and ML-EFA factor loadings obtained in Table 1. At first glance, the two solutions are very different. Clearly, the ML loadings look more understandable. There is only one loading of medium magnitude. All the rest are either very small (< 0.1), or large, with three near unity. In contrast, almost all LS loadings are of rather medium magnitude, and thus difficult to interpret. A possible way out, at least for small data sets, is to plot and inspect the factor loadings for some interesting patterns. We plot these LS and ML solutions respectively on the left and the right panels of Fig. 3. It is easy to see that both solutions form very similar configurations of points on the plane. This indicates that, in fact, the LS- and ML-EFA solutions are very close. We will see in the next sections that this can be explained in formal terms.

Table 1 Two EFA solutions for Five Socio-Economic Variables.

Fig. 3 Plots of factor loadings from two EFA methods.

Simple structure concept

The EFA model (2) is not unique. Indeed, it can be rewritten as:

$$X \approx F\Lambda^T + U\Psi = FQQ^{-1}\Lambda^T + U\Psi = (FQ)(\Lambda Q^{-T})^T + U\Psi,$$

where Q is any $r \times r$ non-singular matrix, i.e. $\det(Q) \neq 0$ and $Q^{-T} \equiv (Q^{-1})^T$. Now, we can recalculate the EFA correlation model (3) in the new notations as follows:

$$\begin{aligned} X^T X \approx R_{XX} &= (FQQ^{-1}\Lambda^T + U\Psi)^T (FQQ^{-1}\Lambda^T + U\Psi) = \\ &= \Lambda Q^{-T} Q^T Q Q^{-1} \Lambda^T + \Psi^2 = \\ &= (\Lambda Q^{-T})(Q^T Q)(\Lambda Q^{-T})^T + \Psi^2, \end{aligned}$$

where ΛQ^{-T} is the new transformed factor loading matrix and $Q^T Q$ is the covariance matrix of the transformed common factors FQ .

The most frequent EFA choice for Q is an $r \times r$ orthogonal matrix, that is, $Q^T Q = Q Q^T = I_r$ and $Q^{-1} = Q^T$. Such matrices express either rotation or reflection, but in both cases they preserve lengths and angles. Note that for orthogonal Q , the transformed common factors FQ remain uncorrelated.

Another popular EFA choice are the $r \times r$ non-singular matrices Q for which $Q^T Q$ is a correlation matrix, i.e. $\text{diag}(Q^T Q) = I_r$. Such matrices are called obliques, because the transformed common factors FQ are not mutually orthogonal. In EFA, such Q s are called oblique rotations.

It is a long tradition in EFA to benefit from this lack of uniqueness of its model. It opens the opportunity to transform the initial loadings Λ into new ones, which are possibly easier to interpret, by making use of orthogonal and/or oblique rotations. However, to do this in an objective manner, we need to define the meaning of “easier to interpret”.

For this reason, the concept of simple structure was introduced in EFA (Thurstone, 1947, p. 335). In more contemporary language they look as follows (Harman, 1976, p. 98):

1. Each row of the factor matrix should have at least one zero,
2. If there are r common factors each column of the factor matrix should have at least r zeros,
3. For every pair of columns of the factor matrix there should be several variables whose entries vanish in one column but not in the other,
4. For every pair of columns of the factor matrix, a large proportion of the variables should have vanishing entries in both columns when there are four or more factors,
5. For every pair of columns of the factor matrix there should be only a small number of variables with non-vanishing entries in both columns.

It makes sense to remind here that the mathematical meaning of vanish is “to become zero” (Webster’s II, The Riverside Publishing Company, 1984). In modern jargon, the simple structure concept, in fact, requires sparse loadings. Broadly speaking the vector $a \in \mathbb{R}^p$ is called sparse if the number of its non-zero entries is very small compared to p . Unfortunately, such a clear-cut sparseness can not be achieved by the rotation methods. The best they can do is to make the loadings’ magnitudes more distinguishable.

Simple structure criteria and rotation methods

Let us take a closer look at how the simple structure concept is implemented in rotation methods. To make the interpretation process objective, analytic rotation methods were introduced (Thurstone, 1947, XVII). At the heart of these methods is the simplicity criterion, which is supposed to express the Thurstone’s five rules in a single mathematical formula. Unfortunately, it turns out that this is a very difficult task. As a result there exists a huge number of criteria, because none of them is capable to produce satisfying solution for every problem.

Table 2 Two VARIMAX rotated loadings and the orthogonal matrices used to rotate the corresponding initial factor loadings from Table 1.

VARS	LS-EFA		ML-EFA	
	I	II	I	II
POP	0.020	−0.995	0.021	0.997
SCH	0.902	0.001	0.898	0.004
EMP	0.144	−0.976	0.137	0.972
SER	0.790	−0.420	0.798	0.423
HOU	0.961	−0.002	0.962	0.001
Rotation	0.793	−0.610	0.999	−0.047
Matrix <i>Q</i>	0.610	0.793	0.047	0.999

Arguably the most popular rotation criterion is VARIMAX (Mulaik, 2010, p. 310). It produces satisfactory results in many applications and is based on a simple to explain concept. Let $\Xi = \Lambda Q$ be the $p \times r$ matrix of orthogonally rotated factor loadings. The variance of the squared loadings of the j th rotated column ξ_j is:

$$V_j = V(\xi_j^2) = \sum_{i=1}^p \xi_{ij}^4 - \frac{1}{p} \left(\sum_{i=1}^p \xi_{ij}^2 \right)^2, \quad j = 1, \dots, r. \quad (8)$$

The variance V_j will be large if there are few large squared loadings and all the rest are near zero. The variance V_j will be small when all squared loadings have similar magnitudes. The VARIMAX rotation problem is to find an $r \times r$ orthogonal matrix Q such that the total variance $V = \sum_{j=1}^r V_j$ is maximized.

We apply varimax from fungible to rotate the LS-EFA and the ML-EFA factor loadings depicted in Table 1. The resulting VARIMAX loadings are given in Table 2. The rotated loading are nearly identical, which formally confirms our conclusion after observing the plots of the initial loadings in Fig. 3. We note that the orthogonal matrix Q that rotates the ML initial loadings is nearly the identity I_2 , that is, the initial ML loadings nearly maximize the VARIMAX criterion and need very “little” rotation.

Rotation to simple structure target

There are a number of alternative rotation methods which do not rely on any particular simplicity criterion. Instead, they “refine” some initial or rotated solution Λ . They construct a target matrix $\mathcal{Y}$ reflecting the simple structure of the problem, based on the already available loadings Λ . Then, transformed factor loadings are obtained by orthogonal or oblique rotation of Λ such that to match the target $\mathcal{Y}$ as close as possible.

PROMAX is probably the most popular method of this kind and constructs a target $\mathcal{Y}$ with elements $v_{ij} = \lambda_{ij}^5 / |\lambda_{ij}|$ (Mulaik, 2010, p. 342–347). As $|\lambda_{ij}| \leq 1$, the magnitudes of the small loading become smaller, while the larger ones remain relatively large.

The VARIMAX loadings found in Table 2 show that both EFA solutions agree in their interpretation, which is also quite unambiguous. In this sense, looking for their “refinement” is not really necessary, but we are interested to see PROMAX in action. We apply promaxQ from fungible with the suggested “fourth power” target. What happens is that first $\mathcal{Y}$ is constructed from the VARIMAX loadings from Table 2. Then, an oblique rotation is found to transform and make them as much like the target $\mathcal{Y}$ as possible. The resulting “refined” factor loadings are given in Table 3.

The PROMAX factor loadings from the two EFA methods are practically identical. The transformed common factors are correlated, and the correlations are also very similar.

Table 3 Two PROMAX factor loadings refining Table 2 and the correlations between the LS and ML oblique common factors.

Concluding remarks

The article introduces the EFA model and its main aspects. The EFA of a small data set gives a flavor and illustrates its application to a real problem. In reality, before doing EFA one is likely to face a preprocessing stage and deal with missing data and/or outliers. They affect considerably the sample correlation matrix, and thus, invalidate the EFA results.

It is understandable, that there is a great number of theoretical and applied EFA details that are left untouched in this article. The provided references can be starting point for a deeper study of EFA. In addition, many specialized issues can only be found in research papers. For example, we already know that EFA is derived and works with continuous data. There are ways to adapt EFA for data from questionnaires with dichotomous or discrete variables, or even multi-level data. Of course, such issues cannot be accommodated in this introductory article.

Introduction

Confirmatory factor analysis (CFA) is a technique used to analyze the efficacy of measurement models where the number of factors and their direct relationship is specified. Conducting CFA requires an *a priori* strategy where a hypothesized factor structure is assessed by evaluation of model fit to empirical (or simulated) data. Application of CFA involves confirming that variables (e.g., items or total test scores) fit a particular pattern or cluster to form a certain dimension according to theory (McDonald, 1999; Fabrigar and Wegner, 2012). Also, researchers synthesize information about the factors and their contribution reflected by examinee performance on the observed variables (e.g., scores on tests or other measurement acquisition formats). Researchers using CFA attempt to understand *why* the variables are correlated and the *degree* or level of accuracy variables and factors provide relative to a theory (Price, 2016).

Application of confirmatory factor analysis (CFA) involves defining a latent variable of interest-based on theory or acquired knowledge. Researchers then construct observed variables (e.g., test items or other variables) to measure continuous latent variables (a.k.a. factors). The selection of a scaling model and variable construction follows sound principles based on rules of correspondence in consideration of properties and levels of measurement (Torgerson, 1958; Krantz et al., 1971). Confirmatory factor analysis is a special case of the common factor model. This model postulates that total scores or test items correlate because they are determined in part from common but unobserved influences. These common influences are due to common factors meaning that variables are correlated to some degree. The unobserved influences manifest as a latent factor (or simply a *factor*) in CFA.

Traditionally, conducting CFA involved developing a measurement model or models within the tradition of structural equation modeling (SEM) to provide validity evidence of scores on tests or other measurement instruments or protocols (Floyd and Widaman, 1995). During the past 30 years, the confirmatory analytic framework has evolved substantially. It includes (a) multilevel CFA (Heck and Thomas, 2015), (b) second and higher-order CFA, (c) bifactor CFA, (c) Bayesian CFA (Kaplan, 2014), (d) longitudinal CFA (Little, 2013; McCardle, 2007), and (g) dynamic CFA of intra-individual change Browne and Zhang (2007) and Molenaar (2004). This article provides an overview of some of these approaches and recent developments in the CFA framework.

Data considerations

Initially, factor analysis was suited for variables scaled on an interval level of measurement and that the variable distributions were assumed to adhere to linear model assumptions (e.g., normality and linearity). However, item-level factor models that include items measured at the binary or ordinal level are now commonly estimated (Flora and Curran, 2004; Muthén, 1984; Muthén and Kaplan, 1985), as are models with nonnormally distributed data.

Sample size and power

As previously noted, CFA is conducted using structural equation modeling (SEM). Planning for an adequate level of statistical power in any study using SEM is critical. Frequently, the use of SEM involves testing or confirming hypotheses about relationships in measurement models (e.g., in test or instrument development, Price, 2016) and among structural relations in a full SEM (Wang and Wang, 2012). Planning for adequate statistical power in a CFA is crucial because it is a hypothesis-driven approach targeting

confirmation of an apriori hypothesis or hypotheses. Specifically, sufficient statistical power in CFA is necessary to ensure that the precision and stability of standard errors and parameter estimates are accurate and do not contribute to inflated Type I and II error rates of hypothesis tests (Barker et al., 2015). Like other inferential statistical methods, estimating statistical power apriori involves determining the minimum required sample size to achieve the maximum level of power for a hypothesized effect size under a specified level of statistical significance (Wang et al., 2013). Estimation of statistical power in CFA (and SEM generally) depends on (a) if the study design is cross-sectional or longitudinal, (b) the number of relationships among test items or variables, (c) reliability of scores based on test items or variables, (d) level of measurement of indicator variables—continuous, ordered categorical or dichotomous and the statistical estimator used (e.g., ML, WLSMV, Robust ML, etc.), (e) magnitude of the factor loadings, (f) pattern and amount of missing data, (g) whether indicator variables are individual items or composites or aggregates of items (e.g., sum scores, average scores, parcels or testlets), and (h) model complexity. Although SEM (and CFA conducted with SEM) is a large sample multivariate method, excessively large samples are costly to acquire and often overstate negligible effects. The challenge in planning for adequate power is to strike a balance between obtaining a sample that is too small to detect essential or hypothesized effects and one that is too large, resulting in wasted time, energy, and resources. However, when a large sample is available, researchers can conduct cross-validation of the CFA thereby providing greater evidence of the tenability of the model (Price et al., 2002; Tulskey and Price, 2003). For guidelines on sample size requirements in CFA see Brown (2015), Wolf et al. (2013), MacCallum et al. (1999), Marsh and Hau (1999), Boomsma (1985). Muthén and Muthén (2002) provide an example of how to conduct power analysis using Markov chain Monte Carlo (MCMC) approach. The MCMC simulation approach to power estimation for model parameters is particularly useful in multilevel and complex factor and structural equation models.

The common factor model

Factor analysis is an essential technique for investigating relationships between constructs (i.e., unobservable underlying attributes or processes) and observed indicators (e.g., test items or other observed measures). The common factor model provides a mathematical framework linking observations of an underlying process to the theory that provides understanding and synthesis. A common factor is a latent variable or factor that influences more than one observed variable. For example, Y1–Y3 are influenced by the η_1 latent variable or factor, and Y4–Y6 are influenced by the η_2 latent variable or factor. The common factor model in Fig. 1 is a two-factor oblique model because the latent variables or factors are correlated (e.g., a double-headed arrow connecting the two factors exists).

Using factor analytic techniques such as CFA, researchers can evaluate how latent or unobservable constructs such as intelligence, achievement, aggression, depression, leadership style, personality traits, etc. affect the daily lives of individuals in various settings. In structural equation modeling, a measurement model is a confirmatory factor analysis model that specifies a set of theoretically informed relationships between a latent variable or factor and observable indicators reflecting intricate, unique information about that factor. Fig. 1 depicts an oblique two-factor CFA.

The general form for the measurement model in a CFA is expressed in Eq.(1) (Heck and Thomas, 2015) as

$$y_i = v + \Lambda \eta_i + e_i \quad (1)$$

In Eq.(1), persons or subjects are indexed by the subscript i , with y_i representing a p -dimensional vector of observed dependent variables, v is a p -dimensional vector of measurement intercepts, η (eta) is an m -dimensional vector of latent variables, Λ (lambda) is $p \times m$ matrix of factor loadings, and e_i (epsilon) is a $p \times 1$ vector of measurement errors (Raykov and Marcoulides, 2006; Heck and Thomas, 2015). Measurement errors are uncorrelated with factors but can correlate with other errors of measurement based on research design or measurement protocols. However, models with extreme flexibility in measurement error may not be identified statistically. Assuming $E(e_i) = 0$, the mean structure is defined as

$$\mu = v + \Lambda \alpha \quad (2)$$

In Eq.(2), note the addition of α , which is a vector of factor means of dimension m .

The covariance structure is

$$COV(y) = \Lambda \Psi \Lambda' + \Theta \quad (3)$$

In Eq.(2), Ψ (psi) is a matrix of factor variance and covariances, and Θ is a $p \times p$ covariance matrix of normally distributed residuals with mean zero and variance of some magnitude (Heck and Thomas, 2015).

The goal of CFA is to reproduce the relationships among indicators with as few parameters required for the estimation process as possible. Confirmatory factor analysis works by imposing theory-driven constraints into the common factor model. Specifically, in CFA, develops and tests a model by prespecifying the number of factors, the pattern of loadings and appropriate error structure (e.g., allowing correlated indicator errors due to a measurement-driven method effect). For example, in Fig. 1, indicators Y1–Y3 load only on factor 1 (η_1) and Y4–Y6 load only on factor 2 (η_2), no cross-loadings exist (i.e., the restriction in the CFA is that cross-loadings are fixed at a value of zero). The simple structure in Fig. 1 is achieved by the specification of each factor loading on a unique set of indicators. In some parameterizations (depending on the specific program used) factor correlations are estimated by default in models with two or more factors. Parameter estimation proceeds by evaluating the sample covariance matrix (S) relative to the model implied population covariance $\Sigma(\theta)$ matrix using $F[S, \Sigma(\theta)]$ yielding a minimum fit function (F_{min}) that indexes the location

Note. A common factor is a factor that influences more than one observed variable. For example, Y1 – Y3 are influenced by the η_1 latent variable or factor and Y4 – Y6 are influenced by the η_2 latent variable or factor. The common factor analysis model above is oblique because the latent variables or factors are correlated (e.g. a double-headed arrow connecting the two factors is present).

Fig. 1 Two-factor model.

in the estimation process where the difference between S and $\Sigma(\theta)$ is the smallest. However, most often estimation proceeds using the method of maximum likelihood (ML), where the likelihood is induced by parametric assumptions of the latent variables and residuals. In the case where indicator variables are nonnormally distributed, alternative estimators are available (e.g., see [Muthén and Muthén, 2007–2010](#)) as are estimators that produce rescaled chi-square fit statistics. After estimation of model parameters, the tenability of results assessed by interpretation of adequacy of model-data fit using model fit statistics such as overall chi-square test, comparative fit index (CFI), and the Root Mean Square Error of Approximation (RMSEA) and associated levels of confidence. Additional fit statistics are available and produced by SEM programs and may be useful depending on the research goal and model specification. For guidance on use of fit statistics post estimation see [Brown \(2015\)](#).

Multilevel confirmatory factor analysis

In standard CFA, observations or measurements are structured at a single level with the assumption that they are statistically independent and identically distributed. However, in many instances, research calls for conducting CFA in settings where individuals are clustered or nested within organizations (e.g., schools, businesses, healthcare settings, or other organizations). Also, measurements on individuals are often nested within individuals either cross-sectionally or longitudinally. Multilevel CFA (ML-CFA) provides a multilevel measurement modeling framework that accounts for clustering or nested structures in CFA resulting in, for example, analyses of construct validity and measurement invariance at different levels of measurement (i.e., at level-1 vs. level-2). An essential use of multilevel modeling is to determine whether the effects at level-1 (micro-level) are the same as those at level-2 (macro-level; [Sniders and Bosker, 1999](#)). For example, is it correct or reasonable to assume the factor structure holds equally well (i.e., is invariant) across different schools, businesses, healthcare settings, etc.? If the answer is no, to what degree do the level-2 units vary? When parameter estimates of the CFA model are restricted to be the same (or have little variation) at both levels-1 and 2, the result is a fixed-effects model with no need to estimate and interpret variation across level 2 units or clusters. If the parameter estimates level-1 are allowed to vary across level-2, the result is a random-effects or random coefficients model. The ML-CFA model also allows for the inclusion of covariates at level-1 and level-2 to investigate hypothesized effects that may influence the parameter estimates at either level (e.g., see [Fig. 2](#)). Extending the initial CFA in [Fig. 1](#), consider a two-factor CFA model that measures the level of writing

Note. The symbols $B\eta_1$ and $B\eta_2$ in the upper half of the figure signify the group-level factors. The bottom half of the figure represents the within-subjects factor model. The Y variables remain consistent across levels. In the within model, solid circles on arrows are random slopes and on Y variables are random intercepts. In the between model, random slopes are depicted as circles or latent variables varying across teachers or clusters. $\beta_{Y1} \dots \beta_{Y6}$ at the level-2 represent intercepts.

Fig. 2 Multilevel confirmatory factor analysis model with covariates.

fluency (Factor 1: Y1–Y3 are measures of fluency) and essay composition (Factor 2: Y4–Y6 of writing composition) in middle school for student with disabilities as the outcomes at level-1. Evidence from the literature on writing performance reveals that students' level of self-efficacy influences their writing performance. Therefore, student self-efficacy is included at level-1 as a covariate to test the within-subjects effect of self-efficacy as a predictor of writing fluency and composition. At level-2 (between-clusters or teachers), teachers' self-efficacy related to teaching writing serves as a covariate. The research questions are: Does student writing performance in fluency and essay composition vary across teacher classrooms? Is teacher level of self-efficacy (level-2 covariate) a significant predictor the student writing performance in fluency and essay composition? Is student level of self-efficacy (level-1 covariate) a significant predictor of student writing performance in fluency and essay composition?

Muthén (1991, 1994) provided a general framework for the analysis of multilevel covariance structures for SEM. Following Muthén's framework, analysis of the ML-CFA in Fig. 2 involves analysis of a total variance-covariance matrix representing a single population that can be disaggregated into within-person and between-groups matrices reflecting levels-1 and 2 of the hierarchy (see Fig. 2). Total scores for persons at level-1 capture the variation within-persons (i.e., using the deviation of each person's score from the group mean) and a between-group matrix that captures group-level mean composition. In the level-1 or within-part of the model in Fig. 2, the regression of the two factors on the student-level covariate self-efficacy captures variation in the random slopes for students (solid dots marked as S1 and S2). The level-1 random intercepts (displayed as solid dots on the Y variables) capture how means on the variables randomly vary across students. In the level-2 (between part of the model), the regression of the two factors on the teacher-level covariate self-efficacy captures the random variation across teachers (clusters) for each factor. The within and between matrices are orthogonal and additive as in other linear modeling frameworks (e.g., linear mixed-models). Eqs.(4)–(9) follow (Heck and Thomas, 2015; Muthén, 1991, 1994). The ML-CFA overall population equation for person i in cluster j is

$$\text{COV}(y_{ij}) = \Sigma_T = \Sigma_B + \Sigma_W \quad (4)$$

The subscripts T , B , and W represent the total, between-cluster, and within-group covariance matrices. Decomposition of the total matrix is expressed as the between-cluster covariance matrix is

$$\Sigma_B = A_B \Psi_B A_B' + \Theta_B \quad (5)$$

the within-group covariance matrix is

$$\Sigma_W = A_W \Psi_W A_W' + \Theta_W \quad (6)$$

Finally, factor means are modeled at the cluster level as

$$\mu_j = A_j \alpha \quad (7)$$

Returning to Fig. 2, I provide an overview of how the ML-CFA analysis proceeds. The multilevel measurement model in Fig. 2 is

$$y_{ij} = v_j + A \eta_{ij} + \varepsilon_{ij} \quad (8)$$

In Eq.(8), y_{ij} represents the vector of variables Y1–Y6, v_j $p \times 1$ vector of intercepts, v is a p -dimensional vector of measurement intercepts, A (lambda) is $p \times m$ matrix of factor loadings, η_{ij} (eta) is an m -dimensional vector of latent factors, and ε_i (epsilon) is a $p \times 1$ vector of residuals errors (Raykov and Marcoulides, 2006; Heck and Thomas, 2015). Independence in observations is assumed at the cluster or teacher level—not the level of individual persons.

Latent factor means randomly vary across teachers as

$$\eta_{ij} = \alpha + \eta_{Bj} + \eta_{Wij} \quad (9)$$

where α is the grand mean for all η_{ij} , η_{Bj} is a randomly varying factor component capturing teacher effects, and η_{Wij} is a random factor for students that varies within teachers. The structure of this framework provides a partition of the variability of students' scores into (a) between teachers (capturing the teacher effect) on scores or outcomes. Students' scores are group (teacher-centered), rendering them uncorrelated. Finally, the between-teachers and within students' covariance components are independent like the random effects analysis of variance model providing a way to estimate the random effect of teachers' conditional on student i residing in a specific teacher classroom j . For details on ML-CFA model specification (including program coding in Mplus), estimation and interpretation of results, see Heck and Thomas (2015). The ML-CFA can also be extended to longitudinal models. For details on model specification, estimation, and interpretation for the longitudinal ML-CFA see Little (2013).

Second-order factor analysis

In contrast to the two-factor oblique model in Fig. 1, a second-order CFA provides an alternative way to evaluate the factor structure where multiple factors exist. A second-order factor model is appropriate when first-order factors are explained by a higher-order structure (Schumacker and Lomax, 2010, p. 271). In keeping with CFA tradition, the application of a second-order structure is informed by theory to justify its use. Recall that in a single level CFA, including only first-order factors, the focus is on the measurement model that maps the items or indicator variables onto a hypothesized latent or factor structure. Provided a first-order structure

Fig. 3 Second-order CFA.

is tenable, in a second-order CFA, the focus is on the intercorrelations and/or linear relations among the factors rather than the item or variable relationships with the factors.

An example of a second-order CFA is provided in Figs. 3 and 4. Factors and indicator variables in the model are based on a small subset of data based on the general theory of intelligence (Gf/Gc) presented in Price (2016). In Fig. 3, the four first-order factors are Vocabulary, Knowledge, Graphic Orientation, and Graphic Identification. These factors are latent indicators of second-order factors of Crystallized Intelligence and Fluid Intelligence. The two second-order factors are predicted to account for the correlations among the first-order factors. According to the general theory of intelligence, Crystallized and Fluid Intelligence are posited to be distinct yet positively correlated parts of intelligence. The tenability of the second-order CFA should be substantiated by the pattern of correlations among the first-order factors. For example, relatively high, positive correlations are expected between the first-order factors comprising Crystallized Intelligence (Vocabulary and Knowledge) and Fluid Intelligence (Graphic Orientation, and Graphic Identification). However, only moderate, positive associations are expected between the first-order factors Vocabulary and Knowledge when correlated with Graphic Orientation and Graphic Identification.

The second-order CFA in Fig. 3 includes the following assumptions. First, first-order factors, Vocabulary, Knowledge, Graphic Orientation, and Graphic Identification are continuous latent variables or factors. Intercepts and residual variances (e) of the indicator variables comprising the first-order factors are freely estimated as are the residual variances (a.k.a. disturbances) of the first-order factors (E). Error variances of indicator variables and first-order factors are uncorrelated. Finally, second-order factors freely correlate based on empirical and theoretical considerations.

The general sequence for conducting a second-order (or higher-order) CFA includes (1) developing a conceptually valid, well-fitting first-order model, (2) examining the pattern of correlations among first-order factors, (3) fit the second-order model based on empirical and theoretical grounds (Brown, 2015, p. 290). Review of results of the analysis with the example data for a four-factor oblique CFA provide evidence that the model fit is acceptable (e.g., $\chi^2(66) = 108.59, p < 0.001$, CFI = 0.97; RMSEA = 0.04; 90%

Chi-square = 109.50, df = 49, $p = 0.00$; Comparative Fit Index = .97; Root Mean Square Error of Approximation = .04 (90% C.I.: .03 - .04).

Fig. 4 Second-order CFA standardized solution.

C.I.: 0.03–0.04). Furthermore, all factor loadings on the indicators display reasonable magnitudes. The pattern of the correlations among the four first-order factors (not shown in Fig. 4) supports the tenability of proceeding with fitting a second-order CFA. For example, the correlation between Knowledge and Vocabulary is 0.78. However, the correlations between Vocabulary and Graphic Orientation and Graphic Identification are moderate at 0.49 and 0.41, respectively.

Similarly, the correlations between Knowledge and Graphic Orientation and Graphic Identification are moderate at 0.41 and 0.39 respectively. Importantly, the observed patterns of correlations among the first-order factors generally align with the *GfGc* theory of intelligence (i.e., if the first-order correlations among factors were all equal or approximately so, there would be no need for a second-order CFA). Finally, the Schmid-Leiman (1957) transformation can be applied to the standardized solution in a second-order CFA if a researcher is interested in the relationship on the second-order factor(s) to observed indicator variables. For example, the effect of Crystallized Intelligence (second-order factor) on observed variable V1 is obtained as $0.94(0.49) = 0.46$. The value of 0.46 is interpreted as a total effect or as a mediated effect (e.g., Vocabulary mediates the relationship between Crystallized Intelligence and V1). An excellent treatment on the application and interpretation of the Schmid-Leiman transformation in higher-order CFA is provided in Brown (2015).

Confirmatory bifactor analysis

The bifactor model (Reise, 2012; Chen et al., 2006; Harman, 1976) provides another way to examine CFA models with second- or higher-order structures. In a bifactor model, a general factor exists that accounts for significant covariance in observed indicator

variables. Also, specific domains exist that account for unique variance in the indicators of a particular domain over and above the general factor. [Reise \(2012, p. 668\)](#) notes that bifactor models are well-suited for modeling construct-relevant multidimensionality that arises in responses to measures of broad constructs where multiple distinct domains of item content are included to increase evidence of content-related validity. To this end, bifactor models provide a cogent framework measure construction and conceptualization and for the psychometric evaluation of measures existing in multidimensional models. Importantly, there is a connection between the bifactor and second-order CFA. The second-order model in [Figs. 3 and 4](#) is nested within the bifactor model, a characteristic of the model that provides a way to compare a bifactor baseline model to a second-order CFA. To illustrate the bifactor model, I reconfigure the second-order CFA in [Figs. 3 and 4](#) as depicted in [Fig. 5](#).

[Fig. 6](#) provides the standardized solution to the bifactor model in [Fig. 5](#). The fit of the bifactor model is worse than that of the second-order model as evidenced by a smaller CFI and larger RMSEA. Additionally, the difference between the chi-square model fit statistics for the two models is 67.76 (177.26, bifactor, and 109.50, second-order) with a difference in degrees of freedom of 7 (statistically significant at $p < 0.01$). Also, in the bifactor model, the variance of the Graphic Orientation factor is insignificant and factor loadings are small in magnitude, indicating that when adjusting for general intelligence, Graphic Orientation does not add significant unique variance to the solution. As a next step, a researcher can eliminate the Graphic Orientation domain factor and rerun the analysis with a respecified bifactor model. This decision to take the step of specifying the model without Graphic Orientation versus using the second-order CFA results depends on the goal(s) of the researcher. However, it is not always easy to determine whether to opt for a second-order model or a bifactor model. For information and guidance on this topic, see [Mansolf and Reise \(2017\)](#). Factor-model based reliability is estimated for bifactor models using OmegaH and OmegaS coefficients ([Reise et al., 2012; McDonald, 1999](#)). In summary, using a nested modeling approach (where the bifactor model is nested within the second-

Fig. 5 Bifactor model.

Chi-square = 177.26, $df=42$, $p<.001$; Comparative Fit Index = .94; Root Mean Square Error of Approximation = .06 (90% C.I.: .05-.07)

Fig. 6 Bifactor model—standardized solution.

order model) to investigate the structure of multidimensional scales provides a comprehensive way to investigate the factor structure of multifactor scales.

Bayesian confirmatory factor analysis

Bayesian CFA is an approach that has recently emerged and provides increased flexibility in CFA. Bayesian probability theory and statistical methods have existed since the 18th century. However, until recently the use of Bayesian statistical methods has been limited. Lack of use of Bayesian methods is due to (a) a different paradigm than that of the well-established long-run (a.k.a. frequentist) school of probability and (b) access to software to enable the use of the methods. The software *Mplus* and R are available to conduct Bayesian analyses. Also, many published articles and books are available to allow researchers to learn and become proficient applied users of Bayesian statistical methods.

Bayesian statistical thinking can be viewed as an extension of the traditional or frequentist approach, in that it formalizes aspects of the statistical analysis that are left to uninformed judgment by researchers in classical statistical analyses (Price, 2016; Lee, 2007). A critical difference between Bayesian and Classical probability is that in the Bayesian framework, the data are fixed and the parameters are random. Conversely, in classical probability, the data are random and the estimated parameters are fixed. Because the parameters estimated in a Bayesian analysis are random, researchers are able to make direct probabilistic statements about (a) point estimates such as the mean, median, mode, or regression weights and (b) random parameters lying within specific upper and lower limits (i.e., credibility intervals). Also, Bayesian credible intervals often contain frequentist coverage probabilities, often being close to Bayesian coverage levels (Lee, 2007).

Attractive features of using Bayesian methods include the following. First, Bayesian estimation does not assume that posterior distributions of parameters are normal (i.e., no reliance on large-sample, traditional statistical theory), making for better performance in small sample size conditions. Second, the estimation of complex models with multiple latent variables (factors) with categorical indicators or mixtures of continuous and categorical is possible where traditional maximum likelihood estimation fails. Third, in scenarios where missing data is present, full information maximum likelihood (FIML) or multiple imputation (MI) are automatically implemented based on the analytic model based on user preference. Fourth, higher statistical power under conditions where the distributions of indicator variables are not normal. Finally, multilevel and mixture models are more easily and accurately estimated. As Marsh et al. (2009, 2012) notes, poor model fit occurs using traditional ML methods in large samples and in multi-dimensional measurement models with a large set of indicators. Therefore, Bayesian CFA is ideal for fitting longitudinal, multilevel, and multiple group analyses where models are often complex.

An example of a second-order Bayesian CFA is provided in Fig. 7. The impetus for this study arose from the observation of perfect model fit in the second-order CFA conducted on the Wechsler Preschool and Primary Test of Intelligence-Fourth Edition (WPPSI-IV; Wechsler, 2012) for ages 2 years, months to 3 years, 11 months ($N = 1100$) during the test development phase (Price, 2017). In the original second-order CFA conducted using traditional CFA with maximum likelihood estimation perfect model fit was observed ($\chi^2 = 2.0(6)$, $p = 0.91$; CFI = 1.0; RMSEA = 0.0; SRMR = 0.0). However, a non-positive definite factor covariance matrix was observed yielding the solution inadmissible. To examine this solution more thoroughly, Bayesian CFA with informative priors was employed to resolve the non-positive definite matrix solution between the measurement and latent variable parts of the second-order model in a way that provided an optimal tradeoff between simple structure and model-data fit.

Recall that in CFA, cross-loadings are constrained to be exactly zero (a requirement often resulting in poor model fit). In Bayesian CFA, parameters such as factor loadings and indicator error variances can be set to near or approximately zero but not exactly at zero without compromising a properly specified measurement model. Model estimation using Bayesian CFA proceeded in the current example by specifying informative priors on cross-loadings (dashed paths in Fig. 7) by using mean zero (0) and normal distributions (N) with small variance (0.01), or formally as $\sim N(0, 0.01)$. Factor variances were set to a value of 1.0 and the metrics of the priors align with standardized loading solutions. The variance of the prior distribution captures the uncertainty about parameter statistics with value of 0.01 yielding a highly informative prior on the magnitude of cross-loadings (e.g., ± 0.03 in a standardized loading metric; Muthén and Asparouhov, 2012). Assignment of the ± 0.03 yields a 95% standardized cross-loading limit of ± 0.28 . Bayesian analysis proceeds by estimating the posterior distributions of parameters using Markov chain Monte Carlo (MCMC)

Note. Heavy bold paths = anchor test; Dotted paths are set to an approximate zero value; Dashed paths are required to allow the assignment of non-zero priors. FS=full scale IQ, VC=vocabulary, VS=visual spatial, WM=working memory.

Fig. 7 Bayesian second-order confirmatory factor analysis.

sampling (e.g., see Gelman et al., 2004 for details). Given the use of MCMC methods in Bayesian analysis, additional evaluation of MCMC convergence to the posterior distribution is required. The convergence of the MCMC algorithm is evaluated by the potential scale reduction statistics (PSR). Gelman et al. (2004) recommends a PSR of 1.10 for all model parameters as evidence of operational convergence. Additionally, a review of convergence plots produced by the MCMC chains is recommended and typically reported in Bayesian structural equation modeling (BSEM), including Bayesian CFA. Finally, Bayesian posterior predictive checking (PPP) is conducted and reflects the discrepancy between the actual data and the posterior distribution replicated by the model (Gelman et al., 2004; Muthén and Asparouhov, 2012). Results of the Bayesian analysis revealed that (a) latent (factor) regressions were inflated in the original second-order CFA, (b) assigning informative priors provided a way to capture the impact of the cross-loadings and account for the skewness in the parameter distributions, and (c) inadmissible solutions due to a non-positive latent variable matrix were eliminated. In summary, Bayesian CFA provided higher sensitivity to model specification informed by theory.

Summary and conclusions

Confirmatory factor analysis is a technique used to analyze the efficacy of measurement models where the number of factors and their direct relationship are specified. Conducting CFA requires an *a priori* strategy where a hypothesized factor structure is assessed by evaluation of model fit to empirical (or simulated) data. Specifically, application of CFA involves (a) confirming that variables (e.g., items or test total scores) fit a particular pattern or cluster to form a certain dimension according to a theory (McDonald, 1999; Fabrigar and Wegner, 2012), and a (b) synthesis of information about the factors and their contribution reflected by examinee performance on the observed variables (e.g., scores on tests or other measurement acquisition formats). Importantly, researchers using CFA attempt to understand *why* the variables are correlated and the *degree* or level of accuracy the variables and factors provide relative to a theory (Price, 2016).

Traditionally, conducting CFA involved developing a restricted measurement model or models within the tradition of structural equation modeling (SEM) to provide validity evidence of scores on tests or other measurement instruments or protocols (Floyd and Widaman, 1995). This article reveals the change and evolution of CFA during the past 30 years. The confirmatory analytic framework has evolved substantially and now includes (a) longitudinal factor analysis (Little, 2013; McCardle, 2007), (b) second and higher-order CFA, (c) bifactor CFA, (c) Bayesian CFA Kaplan (2014), (d) multilevel CFA and (g) dynamic CFA of intra-individual change Browne and Zhang (2007) and Molennar (2004). This article provides an overview of these developments in the CFA framework. Finally, although not included in this article, CFA models are often incorporated into multiple indicator multiple cause (MIMC; Gunzler and Morris, 2015) models and Multitrait-Multimethod (MTMM; Marsh and Grayson, 1995) models in a variety of disciplines.

Structural equation modeling (SEM) is a flexible general modeling framework that encompasses conventional general linear models such as multiple regression and factor analytic models and is capable of many plausible extensions. This article focuses on modeling procedures for the basic covariance structure models that include directional or structural relationships among observed or latent variables. Structural equation modeling generally starts with model specification, followed by estimation, evaluation, and if necessary, modification (e.g., Lei and Wu, 2007; Kline, 2016, pp. 117–118). Important considerations at each step and commonly encountered modeling issues along with recommended guidelines, where applicable, are discussed and illustrated with a concrete example below.

Common SEM terminologies and notations

A general SEM may include a *measurement part*, in which relationships between observed indicator variables and the unobserved latent constructs they purport to measure are stipulated, and a *structural part* that specifies directional relationships among latent and/or observed variables. Fig. 1 illustrates a relatively simple full SEM model. It contains a measurement part in which the item scores (Item 1–Item 5) serve as indicators for the latent construct (reading efficacy) as well as a structural part in which the hypothesized regression relations among the other observed variables (gender, grade, signaling baseline, intervention, signaling posttest) and the latent construct (reading efficacy) are specified. Models that contain only the measurement part are considered a special case and known as *confirmatory factor analysis models* (CFA). CFA is often used to examine internal structure validity evidence

Fig. 1 Conceptual diagram of indirect intervention effect on self-efficacy via learning signaling words.

for measurement scores of latent constructs. *Path models* refer to the application of the structural part only on observed variables and can be considered a multivariate extension of regression to allow simultaneous estimation of multiple outcome variables, mediation effects, and correlated errors.

SEM models in education research are often complex. As pictures speak louder than words, *path diagrams* become an effective medium of communication for model specification. By SEM convention, square or rectangular shapes are used to enclose observed variables in a path diagram and round or oval shapes are used to enclose latent variables. Directional relationships between variables, latent or observed, are indicated by directional arrows with the hypothetical cause pointing to the presumed outcome (i.e., cause → outcome). In SEM, outcome or dependent variables that have other variables pointing directly to them are considered *endogenous* because their variances are being explained in the model (e.g., signaling posttest, reading efficacy, and Item 1–Item 5 in Fig. 1). Explanatory or independent variables that point to other variables only are considered *exogenous* as their variances are not being explained (e.g., gender, grade, signaling baseline, and intervention in Fig. 1). Inter-variable associations unexplained by other variables in the model are connected by bidirectional curvy arrows (↔; e.g., those among the observed exogenous variables). Equation residuals (referred to as *disturbances* in the structural part or *measurement errors* in the measurement part) can be represented by small circles (as they are latent) or simply by small arrows pointing to the endogenous variables in question without source variables.

Model conceptualization and specification

SEM models can be specified to test specific research questions or hypotheses that are developed from literature review of theories, prior research findings, or both. Important considerations for model specification include directions of structural relations, whether observed or latent variables are analyzed, and whether the model is theoretically identified (see definition below). Existing literature and previous findings can often shed light on the direction of structural relations among variables (e.g., whether self-efficacy predicts achievement, achievement predicts self-efficacy, or both in a reciprocal fashion). Timing or order of experimental events and measurements in research designs also helps to inform the direction as events that occur earlier should naturally be possible causes rather than outcomes of later events. Moreover, many constructs in Education and Psychology are not directly observable (e.g., self-efficacy, achievement) but are inferred from participant or informant responses to survey or test items that are designed to tap the latent constructs. As such, indicators (item scores or subscale scores) are reflective of the latent constructs (i.e., latent factors → indicator variables) in CFA or measurement part of SEM models and are called *effect indicators* (Kline, 2016, p. 196).

The choice between modeling observed or latent variables could depend on whether psychometric qualities, particularly internal structures, of the measures are well established in the relevant literature and whether sample size is sufficiently large to incorporate a measurement part which will increase the number of model parameters to be estimated. In general, larger sample sizes are required to provide stable estimates for larger models with more parameters. A common rule of thumb is that sample size should be no less than 10 or 20 times the number of parameters to be estimated in the model (e.g., Kline, 2016, p. 16). When sample size is inevitably small, one way to reduce model size without sacrificing the structural part is to approximate latent constructs by observed scores from well-established measurement scales, which essentially reduces the measurement part to a single-indicator-per-construct CFA. Reliabilities of the measure scores, if available, can be incorporated in the SEM model to account for measurement errors.

Once a model of interest is conceived, it is prudent to check whether it is *identified*. A model is said to be identified if all model parameters can be uniquely estimated. There are some basic necessary conditions for model identification, such as the number of unknowns (model parameters to be estimated) cannot be more than the number of knowns (observed variances and covariances in SEM), every latent variable must be assigned a scale, and a variable cannot be a predictor of itself, but they are not sufficient. Necessary and/or sufficient identification conditions have been established for certain model types (see Kline, 2016, chapters 7, 9, and 10 for more information). In general, reciprocal or feedback relations, correlated errors, complex indicators that cross-load on multiple factors, and small number of indicators for latent factors (e.g., two per factor) are potential causes of under-identification and require special attention.

To illustrate some of the concepts, suppose a researcher would like to test the logic model for a reading intervention program. The intervention program is designed to teach children conjunctive words that signal the type of text structure to improve reading comprehension and reading self-efficacy. In the research design, children were randomly assigned to the intervention or control conditions. Students' knowledge about signaling words were measured at baseline and after the intervention. Besides taking signaling word knowledge tests after the intervention, students were also asked to rate several items about reading self-efficacy on a 4-point Likert type scale. The hypothetical conceptual model is presented in Fig. 1. As the logic model hypothesizes that the intervention program will increase signaling word knowledge which will in turn increase reading self-efficacy, Fig. 1 shows intervention → signaling posttest → reading efficacy with the demographic variables (gender and grade) and the signaling baseline measure controlled for. Intervention also points directly to reading efficacy to allow for partial mediation through signaling posttest. Reading efficacy was latent and indicated by five items in the model. All other variables were treated as observed with the implicit assumption that they were measured without errors, which would likely hold for demographic and intervention condition indicators. Signaling knowledge was not likely measured without errors and could also be modeled as latent with a large sample. However, it was treated as observed (due to reasonably good internal structure evidence) to keep the model simple for illustration purpose. The directional arrows pointing to signaling posttest could be justified by the order of measurement (i.e., the source

predictors were measured prior to the posttest). The path from signaling posttest to reading efficacy was based on the logic model. Because signaling posttest and reading efficacy were measured at approximately the same time, the opposite direction or direct feedback between them could not be ruled out based on time precedence and the results should be interpreted with caution. Nevertheless, the model is theoretically identified because there are more knowns than unknowns, more than three indicators for the reading efficacy factor, and there are no correlated errors or feedback structural relations.

Model estimation

The general SEM model can be expressed as a system of equations. Using Bollen's (1989, p. 320) notation, the measurement part includes: $y = \Lambda_y \eta + \varepsilon$ and $x = \Lambda_x \xi + \delta$,

where y and x are vectors of observed variables; Λ_y and Λ_x are matrices of factor loadings (λ 's) for latent endogenous variables η and latent exogenous variables ξ , respectively; and ε and δ are vectors of measurement errors for y and x , respectively. The structural part given by Bollen (1989, p. 319) is: $\eta = B\eta + \Gamma\xi + \zeta$, where B is a matrix of coefficients (β 's) among the latent endogenous variables with 0 on the main diagonal (i.e., each endogenous variable is allowed to regress on other endogenous variables but not on itself), Γ is a matrix of coefficients (γ 's) between latent endogenous variables and latent exogenous variables, and ζ is a vector of disturbances (or equation residuals or errors). Expected values of errors (ε , δ , and ζ) are zero. Assuming that the latent and observed variables are centered at their means (i.e., not modeling mean structures), and errors are uncorrelated with the latent variables and with each other (see Bollen, 1989, p. 320 for more details), the covariance matrix among observed variables can be written as a function of the model parameters (Bollen, 1989, p. 325):

$$\Sigma = \begin{bmatrix} \sum_{yy} & \sum_{yx} \\ \sum_{xy} & \sum_{xx} \end{bmatrix} = \begin{bmatrix} \Lambda_y(\mathbf{I} - \mathbf{B})^{-1}(\Gamma\Phi\Gamma' + \Psi)[(\mathbf{I} - \mathbf{B})^{-1}]'\Lambda_y' + \Theta_\varepsilon & \Lambda_y(\mathbf{I} - \mathbf{B})^{-1}\Gamma\Phi\Lambda_x' \\ \Lambda_x\Phi\Gamma'[(\mathbf{I} - \mathbf{B})^{-1}]'\Lambda_y' & \Lambda_x\Phi\Lambda_x' + \Theta_\delta \end{bmatrix} \quad (1)$$

where $\mathbf{I}$ is an identity matrix, $(\mathbf{I} - \mathbf{B})$ is nonsingular, Φ is the covariance matrix for ξ , Ψ is the covariance matrix for ζ , Θ_ε and Θ_δ are covariance matrices for ε and δ , respectively. Therefore, factor loadings in Λ_y and Λ_x , path coefficients in $\mathbf{B}$ and Γ , variance-covariance elements among errors in Θ_ε , Θ_δ , and Ψ , as well as variance-covariance elements among latent exogenous variables in Φ are model parameters to be estimated.

Most applications do not need all matrices mentioned above or all elements in them. Non-applicable elements would become zeros, and some values are fixed to known constants for identification purpose (e.g., one λ for each latent variable is commonly fixed to 1 or the factor variance is fixed to 1 to provide a scale for the latent variable; the diagonal elements of $\mathbf{B}$ are fixed to 0 as an endogenous variable cannot be a cause for itself). For the model depicted in Fig. 1, because the exogenous variables are not latent, $\Lambda_x = \mathbf{I}$, $\Theta_\delta = \mathbf{0}$, $x = [\text{gender, grade, signaling baseline, intervention}] = \xi$, and Φ will take the values of the observed variances and covariances among the x -variables. The measurement model for y is,

$$y = \begin{bmatrix} \text{Item 1} \\ \text{Item 2} \\ \text{Item 3} \\ \text{Item 4} \\ \text{Item 5} \\ \text{SgnlPo} \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ \lambda_{21} & 0 \\ \lambda_{31} & 0 \\ \lambda_{41} & 0 \\ \lambda_{51} & 0 \\ 0 & 1 \end{bmatrix} \begin{bmatrix} \text{efficacy} \\ \text{ISgnlPo} \end{bmatrix} + \begin{bmatrix} \varepsilon_1 \\ \varepsilon_2 \\ \varepsilon_3 \\ \varepsilon_4 \\ \varepsilon_5 \\ 0 \end{bmatrix}$$

where SgnlPo is signaling posttest, ISgnlPo is a phantom latent variable set to be the same as the observed variable by fixing the loading of SgnlPo on ISgnlPo (i.e., λ_{62} in Λ_y) to 1 and error variance of SgnlPo to 0. The structural part of the model is (SgnlBl is signaling baseline),

$$\eta = \begin{bmatrix} \text{efficacy} \\ \text{ISgnlPo} \end{bmatrix} = \begin{bmatrix} 0 & \beta_{12} \\ 0 & 0 \end{bmatrix} \begin{bmatrix} \text{efficacy} \\ \text{ISgnlPo} \end{bmatrix} + \begin{bmatrix} \gamma_{11} & \gamma_{12} & \gamma_{13} & \gamma_{14} \\ \gamma_{21} & \gamma_{22} & \gamma_{23} & \gamma_{24} \end{bmatrix} \begin{bmatrix} \text{Gender} \\ \text{Grade} \\ \text{SgnlBl} \\ \text{Intervention} \end{bmatrix} + \begin{bmatrix} \zeta_1 \\ \zeta_2 \end{bmatrix}.$$

For readers unfamiliar with matrix notations, the model can be simplified to a set of simple linear equations, one for each of the endogenous variables as a function of the variables (including errors) pointing directly to them. For example, the model in Fig. 1 can be expressed as:

$$\begin{aligned} \text{Item 1} &= 1 * \text{efficacy} + \varepsilon_1 \\ \text{Item 2} &= \lambda_{21} * \text{efficacy} + \varepsilon_2 \end{aligned}$$

$$\text{Item 3} = \lambda_{31} * \text{efficacy} + \varepsilon_3$$

$$\text{Item 4} = \lambda_{41} * \text{efficacy} + \varepsilon_4$$

$$\text{Item 5} = \lambda_{51} * \text{efficacy} + \varepsilon_5$$

$$\text{efficacy} = \beta_{12} * \text{signaling posttest} + \gamma_{11} * \text{Gender} + \gamma_{12} * \text{Grade} + \gamma_{13} * \text{signaling baseline} + \gamma_{14} * \text{Intervention} + \zeta_1$$

$$\text{Signaling posttest} = \gamma_{21} * \text{Gender} + \gamma_{22} * \text{Grade} + \gamma_{23} * \text{signaling baseline} + \gamma_{24} * \text{Intervention} + \zeta_2$$

Model parameters (e.g., the λ 's, β 's, γ 's, variances of ε 's in Θ_ε , and variances of ζ in Ψ for the model in Fig. 1) are estimated by minimizing a fit function which summarizes the discrepancy between the observed covariance matrix and the model implied covariance matrix (the rightmost side of Eq. 1). Different estimation methods differ by the way fit functions are defined and may require different distributional assumptions. Because there is no close-form solution for most SEM models, iterative procedures are generally used to find the set of parameter values that minimize the fit function. Iterative procedures require a set of starting values to begin, and parameter values are adjusted iteratively until some convergence criteria (usually in terms of negligibly small differences in parameter values or fit function values between adjacent iterations) are met. The model chi-square goodness-of-fit test statistic, where applicable, is also a function of the converged fit function value. Starting values and convergence criteria are usually supplied by SEM software programs by default and can be overwritten by users. Because iterative procedures may stop when a local minimum (or maximum for maximum likelihood estimation) is reached, SEM modelers are recommended to try different starting values to ensure that the model converges with the same or largely similar set of parameter estimates.

Choice of estimation methods

An important decision for applied SEM researchers is the choice among estimation methods available in SEM software programs. Practical considerations for estimator choice include, but are not limited to, satisfaction of distributional assumption, measurement scale of the observed (particularly endogenous) variables, sample size, and missing data amount and mechanism. The normal-theory-based maximum likelihood (ML) estimation method is probably the most widely used and the default in many SEM software programs. However, it assumes multivariate normal distribution or no excessive kurtosis of observed variables (e.g., Lei and Wu, 2012), an assumption that is hardly satisfied in practice (Micceri, 1989). Robust versions of ML have been developed to deal with violations of normality. A version of robust ML provides regular ML parameter estimates but incorporates Satorra and Bentler's (1988, 1994) scaled statistics to provide robust standard errors and adjusted model chi-squares. Model chi-squares can be mean-adjusted (e.g., MLM in Mplus) or mean- and variance-adjusted (e.g., MLMV in Mplus), but the mean-adjusted version has been more extensively examined and more commonly used. Although this version of robust ML has been found to perform well for non-normally distributed continuous variables with complete data, it should be noted that it does not address the nonlinearity issue associated with categorical endogenous variables (e.g., McDonald and Ahlwat, 1974; Mislevy, 1986; Lei and Shiverdecker, 2020).

Moreover, full-information maximum likelihood (FIML) estimation method, that is considered one of the current state-of-the-art methods for handling missing data (e.g., Graham, 2009), utilizes a modified likelihood function based on individual data (e.g., Enders, 2001). That is, the default ML in SEM programs is not necessarily FIML and not all ML is FIML. Users should consult manuals of SEM software programs to figure out how FIML is specified (see Lei and Wu, 2012, Appendix 10.1 for some examples). If one encounters both missing data and nonnormality issues, another version of robust ML called MLR can be considered because MLR uses FIML and yields robust statistics (e.g., Lei and Shiverdecker, 2020).

Ordinal variables (Likert-type scales) are commonly used in measurement models where item scores serve as indicators for the latent constructs. If normal-theory-based ML, with or without robust statistics, is used for ordinal endogenous variables, parameter estimates may be biased except perhaps when the number of ordinal categories is large (5 or more) and the scores are symmetrically distributed (e.g., Rhemtulla et al., 2012). In general, categorical estimation methods should be used for ordinal endogenous variables (see Lei and Shiverdecker, 2020 for a brief discussion of different approaches to dealing with categorical data in SEM). In short, categorical endogenous variables need to be explicitly declared as such in SEM software programs to overwrite the default assumption of modeling continuous variables. Both ML and weighted least squares (WLS) estimators can be used with categorical variables but their robust versions are more generally recommended (Lei and Shiverdecker, 2020). Specifically, previous empirical studies have showed that the full WLS requires very large sample sizes to perform well, while robust (or diagonal) WLS tends to outperform full WLS at realistic sample sizes (e.g., Flora and Curran, 2004). WLSMV is a robust WLS that provides mean- and variance-adjusted chi-squares as well as robust standard errors. It is the default estimator in Mplus when categorical endogenous variables are declared and estimates polychoric/polyserial correlations as sample statistics for model estimation. However, WLSMV currently handles missing data by listwise deletion or pairwise deletion and might not be a good choice when missing data amount is not small or missingness is related to observed variables (i.e., MAR; Asparouhov and Muthén, 2010). Full-information ML estimators such as MLR might be better in dealing with missing data.

For illustration purpose, the model presented in Fig. 1 was estimated using a random sample of 1000 observations drawn from a larger study. Sample descriptive statistics for the observed variables are given in Table 1. Frequency distributions of the categorical indicators for the latent variable are shown in Fig. 2. It was clear from Fig. 2 that the 4-point indicator variables were quite skewed and more so for Items 2 and 4. As such, the item scores should be treated as categorical. Three estimation methods available in Mplus and examined by Lei and Shiverdecker (2020) for categorical variables were compared to demonstrate their similarities and differences. The first was MLR without declaring item scores as categorical, a common practice in applied research. The second

Note. Table values on the lower triangle are Pearson correlations. Italicized values on the upper triangle, where applicable, are polychoric (among items) or polyserial (with SgnlPo) correlations. SgnlPo = signaling posttest score; SgnlBl = baseline signaling score; Intrvntn = intervention condition. $N = 1000$.

**Fig. 2** Frequency distributions of item scores for reading efficacy.

was MLR with item scores declared as categorical (MLR-CAT) and used probit link to put estimates on the same standard scale as WLSMV. The third was the default WLSMV with probit link for categorical endogenous variables. The sample size should be sufficient for the model size and these estimators (Lei and Shiverdecker, 2020).

Both unstandardized and standardized (with respect to endogenous and latent variables, STDY) parameter estimates provided by the three estimation methods are shown in Table 2. STDY was chosen because all but one exogenous variable was dichotomous. As expected, the path coefficients between the continuous endogenous variable and the exogenous variables were identical across methods. The largest difference between treating item scores as categorical versus not was found in the factor loadings. Standardized factor loadings provided by MLR without declaring items as categorical were consistently lower than those by MLR-CAT and WLSMV (differences ranged from 0.06 to 0.12). Standardized MLR-CAT and WLSMV estimates were largely similar. Interestingly, differences among methods in other standardized parameter estimates (≤ 0.02) were essentially negligible. Since there was no missing data in this example, the computationally intensive MLR-CAT was not necessary and WLSMV would be preferred.

Model evaluation

Before interpreting results from any model, goodness-of-fit of the model to data should be assessed. A chi-square goodness-of-fit test is available for most estimators. However, the model chi-square statistic (simply the product between the converged fit function value and sample size or sample size minus 1) is very sensitive to sample size. Therefore, alternative fit statistics that are less affected

Est. = standardized estimates (standardizing latent and endogenous variables but not exogenous variables); SE = standard error; SgnlPo = Signaling posttest score; SgnlBI = Signaling baseline score; Intrvntn = intervention condition.

by sample size have been developed and mainly used for overall model fit evaluation in practice. There are two general categories of alternative fit indices for standalone overall model fit evaluation depending on whether comparison to a default, often independent model was used (incremental fit) or not (absolute fit). Because different fit indices might be sensitive to misspecifications in different types of parameters, the consensus is to examine multiple indices from different categories. Kline (2016) recommended reporting a minimum set of four fit statistics: model chi-square, Comparative Fit Index (CFI; Bentler, 1990), Root Mean Square Error of Approximation (RMSEA; Steiger, 1990), and Standardized Root Mean Square Residual (SRMR). CFI is an incremental fit index, and higher values indicate better fit (≥ 0.9 or 0.95 is desirable). An RMSEA value of ≤ 0.05 is considered a “close fit” (Steiger, 1990), ≤ 0.06 is desirable (Hu and Bentler, 1999), and > 0.10 is considered bad (Steiger, 1990). An SRMR value of ≤ 0.08 is desirable (e.g., Hu and Bentler, 1999) and > 0.10 is generally not good. Even though these rough rules-of-thumb might be helpful for understanding the metrics of these fit statistics, they were recommended based on studies under a very limited set of conditions and should not be used rigidly (see Kline, 2016, pp. 268–269 for a list of systematic steps for model fit evaluation).

Regardless of overall (or global) model fit, it is important to evaluate local fit and locate any sources of misfit. Local fit loosely refers to the appropriateness of model estimation results other than global fit statistics. Specifically, it is useful to check parameter estimates (e.g., whether there are improper solutions such as negative variances and greater than 1 correlations, whether estimates are significant and/or in expected directions), standard error estimates (whether they are reasonably small because large values that are improper for the parameters in question often indicate estimation problems or identification issues), R-squares for endogenous variables (to see if their variances are well explained), and residuals (standardized value $> |2|$ or correlation residual > 0.10 suggests non-negligible unexplained association). Model results are interpreted when both global fit and local fit are deemed adequate. Otherwise, the model could be modified to fit the data better.

Post hoc model modification is commonly aided by modification index, which is computed for each fixed parameter in the current model and approximates the amount of model chi-square drop should the fixed parameter be freely estimated (assuming other parameters remain unchanged). Modification indices are often reported along with the corresponding expected parameter change (EPC) values. As modification indices are sensitive to sample sizes, it would be helpful to consider the magnitude of EPC and whether the path in question makes theoretical sense if modification is necessary.

Joreskog (1993) discussed three general modeling approaches to SEM. One is strictly confirmatory such that modeling is considered complete regardless of goodness-of-fit of the hypothesized model to data; well-fitting models are adopted and ill-fitting ones are discarded. This all-or-nothing approach might be risky as the initial conceptualization might overlook paths that have not been the focus of theories or explored/reported in previous research. The second approach utilizes model comparison in which goodness-of-fit between competing models predicted by different theories or hypotheses is compared to determine which one is better supported by data. Comparison of fit between models can be based on information criteria such as AIC or BIC (lower is generally

better) for non-nested models or likelihood ratio chi-square difference test for nested models (see Kline, 2016, pp. 286–287 and p. 281, respectively, for more information). Model choice is usually based on a balance between goodness-of-fit and parsimony because a good fitting parsimonious model is more likely to generalize. The third approach is model generating which refers to the practice of post hoc model modification based on statistical indices. Restricted empirical searches for modification with reasonable justifications are generally acceptable. However, relying on a large number of post hoc modifications to derive a well-fitting model is NOT recommended because it is unlikely to lead to a true model (MacCallum, 1986; MacCallum et al., 1992). Regardless of the modeling approach, it is important to point out that goodness-of-fit does not necessarily mean that the model is true or correct, much like the maxim in basic statistical inference that failing to reject a null hypothesis does not mean it is true. Potentially many alternative models might fit the data just as well or even better.

To demonstrate model evaluation, results for the hypothesized model in Fig. 1 from the three estimation methods provided by Mplus were examined. Table 3 shows the overall model fit statistics available from Mplus and R-squares for the endogenous variables. The model estimated by MLR did not treat item scores as categorical, while the model estimated by MLR-CAT and WLSMV did. The models were not nested, and both AIC and BIC produced for ML estimators favored the MLR-CAT model. This suggested that the item scores should better be treated as categorical. Since the recommended minimum set of global fit statistics were not available for MLR-CAT and both categorical methods yielded largely similar parameter estimates, we focused on results from WLSMV.

Model chi-square was statistically significant indicating that the model did not fit well. However, the other global fit statistics suggested good fit ($CFI = 0.98 > 0.95$, $RMSEA = 0.04 < 0.05$, $SRMR = 0.03 < 0.08$). All model parameter and standard error estimates appeared reasonable (i.e., no out-of-bound or questionable values). Standardized factor loadings were acceptably large (≥ 0.59), and all but three path coefficients were statistically significant ($ps < 0.05$). R-square for reading efficacy and signaling posttest was 0.17 and 0.19, respectively, and considered moderately large using Cohen's thresholds for regression. All residual correlations were small ($\leq |0.076|$ and less than the 0.10 threshold). Modification indices suggested that some of the measurement errors might be correlated. For example, modification index for the error covariance between Item 1 and Item 4 was 17.32 (> 3.84) and standardized EPC was 0.45. Since the correlation residual for the pair was small (0.029) and there was no conceivable explanation for the correlation besides the latent factor, the model was not modified. Local fit was judged to be satisfactory. The large model chi-square was likely due to the relatively large sample size.

As for the hypothesized indirect effect of intervention on reading self-efficacy via signaling word knowledge, the model results appeared to support the hypothesis. The estimated indirect effect was statistically significant ($p < 0.001$). The standardized coefficient of 0.15 suggested that students in the intervention condition were 0.15 standard deviation higher than students in the control condition on reading self-efficacy via signaling knowledge, holding gender, grade level, and baseline knowledge constant. Even though the data did not seem to contradict the hypothesized mediation effect, it should be interpreted with caution because reading efficacy and signaling posttest were assessed at approximately the same time. A longitudinal design that allows model specification based on time precedence would be more suitable for testing mediation effects and require fewer assumptions.

Conclusion

In conclusion, SEM is a popular technique in many disciplines, including Education and Psychology. This article briefly introduces some fundamental concepts of SEM with a focus on covariance structure analysis and provides a modeling tutorial on procedures and related practical considerations. It is the authors' hope that it will inspire more judicious applications of SEM in applied research. It should also be noted that although many research questions can be addressed using the basic covariance structure models introduced here, the SEM field is fast growing and has seen prolific developments of models and estimation techniques. Advanced developments include multilevel SEM (e.g., Asparouhov and Muthén, 2016; Preacher et al., 2010), Bayesian SEM (e.g., Dombrowski et al., 2018; Muthén and Asparouhov, 2012), and exploratory SEM (e.g., Asparouhov and Muthén, 2009; Marsh et al., 2020), to name a few.

Introduction

Cluster analysis refers to a set of exploratory data analysis (EDA) methods for multivariate data, that sort instances into groups of similar items. Cluster analysis (CA) has been used widely in educational research, and applications are increasing due to the surge of interest in educational data mining. Application areas within education have included clustering of schools or other educational institutions, curricula, test items, and students. In particular, students may be grouped according to their similarity on demographic, social, or cognitive attributes, but often are classified based on their test scores, academic attainment or other aspects of their learning history. A highly selective review of these applications is given toward the end of this article, organized by the type of educational problem to which the method has been applied.

In order to better understand both these prior contributions and the potential of clustering methods in educational research, some background material may be helpful. First, the goals and uses of cluster analysis should be considered. Cluster analysis (CA) can be used merely as a technique for exploratory data analysis (EDA) or a data reduction tool, a way of grouping cases described by their profile on a set of variables so that groups of similar cases (clusters) can be analyzed separately, or themselves used as the cases for further analysis. CA is sometimes used for theory confirmation or theory generation, wherein the clusters are taken to indicate important subcategories of the modeled instances. This type of uses is common in education and psychology. Finally, CA is sometimes used in machine learning or learning analytics research as a form of “unsupervised learning,” a way of modeling or mimicking intelligent behavior, specifically the categorization of instances.

Clustering methods can themselves be grouped according to the type of underlying model that is fit: partitions, hierarchical clusterings, or sets of overlapping clusters. Within each of these general types of clustering models, a wide variety of criteria for defining optimal solutions and a wide variety of heuristic optimization methods have been proposed. For example, multivariate mixture models and latent class or latent profile cluster techniques (McCutcheon, 1987; Bauer, 2021) can be viewed as alternative methods to fit partitions. The next section below provides a brief primer on these methodological definitions and distinctions.

An overview of clustering

The general clustering problem can be described as follows. Given a set of conceptual objects, instances or data cases, each described as a vector of values on a set of predictor variables (usually numeric), allocate these instances to a set of clusters so that the instances within each cluster are relatively similar or homogeneous, and any two instances not in the same cluster are relatively dissimilar or

heterogeneous. In educational contexts, the instances may correspond to students, test items, classrooms, or other entities. Thus, a cluster is merely a set of instances, and a clustering (or cluster solution) is a set of clusters. Different types of clustering models can be defined formally in terms of the set relations among the clusters (Carroll and Corter, 1995).

Some clustering methods (e.g., k-means) take as input data a rectangular matrix of multivariate data $\mathbf{X}$, with N rows representing cases or instances (in educational contexts, the cases are often students) and P columns representing variables. Cluster methods are most often used to cluster the *rows* of such a data matrix; i.e., to discover groups of cases or instances that are highly similar. However, cluster methods could also be used to find clusters of *variables* (columns) that have similar patterns across cases or instances (rows). More often, principal components analysis (PCA) or factor analysis (FA) is employed to analyze relationships among the variables. However, factor-analytic rotation methods are often employed to find a more interpretable “simple structure” of factor loadings, wherein each variable heavily loads on only a single factor, and every variable loads on some factor. This type of ideal simple structure is equivalent to describing each factor as a list of associated high-loading variables, thus the PCA or FA solution, interpreted in this fashion, can be viewed as a way to identify a clustering (ideally a partitioning) of the variables. In fact, this is often the goal of a PCA or FA analysis; in applications where the variables are test items, each subset or “cluster” of variables may be taken as an interpretable dimension or subscale of the test. However, cluster methods offer a more direct way to achieve such a grouping of highly associated variables.

Some widely used clustering methods such as the k-means partitioning method and Ward’s method for hierarchical clustering (Ward, 1963) take as input the multivariate data matrix described above. These particular methods attempt to group (multivariate) cases so as to minimize the within-cluster variation and/or maximize the between-cluster variation on each numeric variable. However, other clustering methods, including most methods for hierarchical clustering and for fitting sets of overlapping clusters, take as input a matrix of *proximities*, that is an $N \times N$ matrix giving the similarities, distances, associations, or correlations between each pair of the cases or instances to be clustered. For these methods, if the user has begun with a rectangular $N \times P$ matrix $\mathbf{X}$ of multivariate data, it is necessary to first compute or select some measure of proximity between each pair of cases. Proximity is a general term that includes similarity and distance measures, as well as measures of association. Most statistics packages have functions or procedures to aid in this step of generating a proximity matrix, and some clustering software will perform this step automatically if given a rectangular multivariate data matrix as input. A commonly used measure of distance is the Euclidean distance between cases. For cases i and j , the Euclidean distance in the P -dimensional data space is

$$d(i, j) = \sqrt{\sum_{p=1}^P (x_{ip} - x_{jp})^2}$$

Correlations can also be considered to be a measure of similarity among cases (or variables), although the meaning of negative correlations must be carefully considered.

The choice of a proximity coefficient can have implications for the type of structure that is discovered. For example, measures of correlation are sensitive to the multivariate profile shape, but not to the overall level of the clustering variables. Measures of distance, in contrast, are sensitive to both shape and overall level. Most clustering software packages offer a wide variety of distance, similarity, and association coefficients that can be used to transform multivariate observations into proximities.

Types of cluster models

As already mentioned, cluster methods may be broadly grouped by the type of clustering model or solution they employ, into partitioning methods, hierarchical clustering methods, and methods for fitting sets of (arbitrarily) overlapping clusters. Thus, the term “non-hierarchical clustering” should be avoided, because it is ambiguous.

Partitioning

The most widely used clustering methods are methods for fitting partitions. A *partition* is a set of clusters that are mutually exclusive and exhaustive, meaning that no instance belongs to more than one cluster, and all instances belong to at least one cluster. As a consequence, in a partition each pair of clusters is disjoint (i.e., does not overlap). A partitioning is usually represented as a list of clusters, with each cluster represented as a list of the instances that belong to it. For example, the following list represents a hypothetical partitioning of five animals into three clusters C1, C2, and C3:

C1 = (dog, cat)
C2 = (bat)
C3 = (robin, sparrow)

K-means

The k-means algorithm (Sebestyn, 1962; MacQueen, 1967; Steinley, 2006) is probably the most widely used method to find partitions. It works as follows. The researcher decides on the number (k) of clusters to be fit to the data, and the algorithm begins by selecting some set of instances or cases as initial cluster seeds. These initial seeds could be randomly chosen cases, or well-

separated cases selected by some systematic method. Or, the researcher might select the initial cluster seeds for theoretical reasons or by some other external criterion. The algorithm commences by doing a “sorting pass” to assign all the remaining cases to the nearest cluster (represented by the seed on this first pass). “Nearest” means the cluster with the smallest Euclidean distance from the case in question. In subsequent iterations, the case is assigned to the cluster with the nearest *centroid* (defined as the profile of means on the P variables for that cluster). For cluster k , the centroid vector is

$$\bar{X}_k = [(\bar{X}_1)_k, (\bar{X}_2)_k, \dots, (\bar{X}_P)_k]$$

Following assignment of all instances to the nearest cluster, the cluster centroids are recomputed and another sorting pass commences. This iterative process of sorting and recomputing cluster centroids continues until it stabilizes, meaning that the cluster membership does not change in a sorting pass, at which point the cluster solution is determined.

The k-means algorithm can be thought of as an effective heuristic method for finding the partition into K clusters that minimizes the trace of the $P \times P$ within-cluster sum-of-squares and cross-products matrix W . i.e., if SSW_p denotes the sum of squares within clusters for variable p , and n_k denotes the number of cases in cluster k ,

$$SSW_p = \sum_{k=1}^K \sum_{i=1}^{n_k} (x_{ip} - \bar{X}_k)^2 = \sum_{i=1}^N (x_{ip} - \bar{X}_k)^2$$

$$tr(W) = \sum_{p=1}^P SSW_p = \sum_{p=1}^P \sum_{i=1}^N (x_{ip} - \bar{X}_k)^2$$

This minimization effectively minimizes the weighted average of the variances of the variables within the clusters. And because for each variable $SST = SSW + SSB$, it also maximizes the weighted average sum of squares between clusters (SSB), a measure of cluster distinctiveness.

However, the k-means algorithm is not guaranteed to find the optimal allocation of cases to the K clusters. Thus, it is recommended best practice to run k-means a large number of times for a given specified number of clusters K , using random starting seeds. The solution with the best fit measure (minimal SSW or $tr(W)$) is then taken to be the optimal solution. If the algorithm is run only once, it is best to let the program automatically choose well-separated cases for the initial cluster seeds.

Algorithms for k-means clustering are implemented in all of the most popular statistical packages, for example the QUICK CLUSTER procedure in SPSS, PROC FASTCLUS in SAS, and the *kmeans* function in the R package *stats*.

Latent class cluster analysis

Latent Class Cluster Analysis refers to partitioning clustering performed using Latent Class Analysis (LCA) or Latent Profile Analysis (LPA) methods. LCA and LPA are examples of the general class of techniques known as latent structure analysis (McCutcheon, 1987). Within the clustering field, these types of models are sometimes referred to as mixture models, or “model-based clustering.” The distinction between LCA and LPA is that the former assumes categorical observed variables, and the latter assumed continuous predictor variables. But note that LCA is sometimes used as a term referring to either case. The object of Latent Class Cluster Analysis is to classify each observation or instance into one of a set of mutually exclusive and exhaustive latent classes, i.e., clusters. The inferred class membership is expressed in probabilistic terms, thus these methods are sometimes referred to in the data mining literature as examples of “fuzzy partitioning” algorithms. However, a given observation or instance is generally assumed to be assigned to its modal class or cluster, so the results can be treated deterministically.

Latent Class Cluster models are fit by Maximum Likelihood Estimation, often using the EM algorithm (Dempster et al., 1977). Software to fit the Latent Class Cluster model is available from commercial packages such as LatentGOLD, and also from R packages including *poLCA* and *mclust*. The package *mclust* assumes continuous predictors (the LPA case), while *poLCA* assumes categorical predictors (as in LCA).

Hierarchical clustering

A hierarchical clustering is a set of clusters for which each pair of clusters is either disjoint, or one cluster includes the other (Carroll and Corter, 1995). Put another way, the clusters resulting from a hierarchical clustering form a nested set. A hierarchical clusterings is often displayed as a tree graph or dendrogram (see Fig. 1).

Fig. 1 A hierarchical clustering of five animals displayed as an ultrametric tree graph or dendrogram.

Agglomerative methods for hierarchical clustering

Hierarchical clustering (HC) is usually accomplished by *agglomerative* algorithms, whereby all n instances are initially treated as separate clusters. Then, at each step the most similar pair of instances or clusters are chosen and combined into a new cluster. This process continues until all clusters have been merged into a single cluster. Examples of such agglomerative algorithms include Ward's method (Ward, 1963), single-link, complete-link, and average-link clustering (Sokal and Sneath, 1963; Johnson, 1967). Evaluation studies of hierarchical clustering methods, some conducted with simulated data and some with real data, have tended to show Ward's method and average-link clustering (more specifically, the "unweighted pair-groups method using arithmetic averaging") as yielding the most satisfactory solutions.

In the tree diagram, the "height" of the node joining two clusters is an index of how dissimilar objects in the two clusters are. This node height for clusters is often reported by hierarchical clustering software, and is sometimes referred to as the "fusion coefficient." Interestingly, hierarchical clustering is often applied by researchers as a flexible means of finding partitions. Basically, any perpendicular (vertical) slice through the (horizontally oriented) dendrogram determines a partition (Cortier, 1996). For example, in Fig. 1, one such vertical line determines the partition $C1 = (\text{dog}, \text{cat})$, $C2 = (\text{bat})$, $C3 = (\text{robin}, \text{sparrow})$. Thus, the hierarchical clustering simultaneously determines partitionings with $k = 1$ to N clusters. In fact, Murtagh and Legendre (2014) recommend using hierarchical clustering with Ward's method to identify a good partition level, then seeking to refine that partition solution using k-means.

Algorithms for hierarchical clustering are implemented in most statistical packages. In SPSS, the CLUSTER procedure offers both average-link clustering and Ward's method (single-link and complete-link are also available). Note that the SPSS code for Ward's method is written in such a way as to require inputting a matrix of *squared* Euclidean distances rather than distances (Murtagh and Legendre, 2014). In SAS, PROC CLUSTER offers these methods. In R, several packages provide hierarchical clustering algorithms, with the *hclust* function of package *stats* and the *agnes* function of package *cluster* providing the basic hierarchical clustering methods mentioned above.

Additive trees

The distances in a tree diagram representing a hierarchical clustering satisfy the ultrametric inequality, which states that for any two instances x and y that are in the same branch or subtree, the distance between them ($d(x,y)$) and their distances to any other instance z not in that subtree satisfy the ultrametric inequality $d(x,y) \leq d(x,z) = d(y,z)$. A more general type of tree is the additive tree, which satisfies the more general condition called the additive inequality (Sattath and Tversky, 1977). The additive inequality states that for two objects x and y in one branch of the tree, and object u and v in another, $d(x,y) + d(u,v) \leq d(x,u) + d(y,v) = d(x,v) + d(y,u)$. Graphically, an additive tree resembles an ultrametric tree or dendrogram, but the leaves of the tree may vary in their distance to the root of the tree (see Fig. 2). This allows distances in the tree to reflect unique features of the instances that may make it more or less similar to all other instances in the tree (e.g., "bat" in Fig. 2).

The additive tree is a very general model that can accommodate even unidimensional structures (Cortier, 1996). An additive tree displayed in rooted form can be interpreted as a hierarchical clustering, with additional parameters or object constants (the leaf arcs) that can model an instance being relatively near or distant to the other objects in the tree (see Fig. 2).

Effective algorithms to fit additive trees to proximity matrices include ADDTREE/P (Sattath and Tversky, 1977; Cortier, 1982), GTREE (Cortier, 1998), de Soete's (1983) sequential unconstrained minimization technique, the iterative reduction method (Roux, 1988), and the iterative projection method (Hubert and Arabie, 1995). The last three methods above are implemented in the *ls_fit_addtree* function of the R package *clue*. With these methods, it is recommended to run the function a large number of times with a given data set and to take the best-fitting solution, just as for k-means. The ADDTREE/P and GTREE programs are available in the NETLIB repository of statistical software source code.

Fig. 2 A rooted additive tree representing the proximities among 5 objects, with branches interpreted as clusters.

Overlapping clusters

In an overlapping cluster solution, clusters may overlap in arbitrary patterns. This means that a given case or instance can be a member of 0, 1, or more clusters. An overlapping clustering can of course be represented as a list of clusters. But graphically representing sets of overlapping clusters is not straightforward. One representation involves first plotting points representing the cases or instances in the plane, then representing each cluster by a closed loop. An example is shown below in Fig. 3. Another possible representation is the extended tree (Cortier and Tversky, 1986), in which some clusters are represented as a tree, but others are

Fig. 3 An overlapping clustering of five animal terms, represented by the “loops” convention.

Fig. 4 An overlapping clustering of five animal terms, represented as an extended tree.

indicated by marked segments on the tree branches, as in Fig. 4. For example, “bat” shares a marked segment with “robin” and “sparrow”, presumably because they share the attribute of flight.

Algorithms to fit overlapping cluster solutions include ADCLUS (Shepard and Arabie, 1979), MAPCLUS (Arabie and Carroll, 1980), EXTREE (Cortier and Tversky, 1986), the additive profiles method (Mirkín, 1987), additive biclustering (Wilderjans et al., 2013; see also Van Mechelen et al., 2004) and overlapping k-means (Cleuziou, 2008). Overlapping cluster methods have been little used in education, due to their computational complexity and the fact that few mass-market statistical software packages offer such algorithms. However, the ADPROCLUS package to fit the additive profiles clustering model is available as a MATLAB program (Wilderjans et al., 2011), and the EXTREE program is available as PASCAL source code in the NETLIB repository of statistical software.

In spite of the limited availability of software for fitting these models, overlapping clustering methods seem potentially valuable for applications in education. One reason is that this model is a very general one, subsuming both partitions and hierarchical clustering as special cases. Thus, overlapping clustering methods can be argued to best fulfill the promise of a general “unsupervised learning” technique. Two examples that illustrate this potential are described below, one an application to the problem of inferring a set of cognitive or educational attributes in a diagnostic measurement context, and another involving the discovery of structure in student knowledge of arithmetic.

Data preparation for a cluster analysis

The above descriptions of clustering algorithms and software assume that the input data are either numeric predictors in the form of a rectangular multivariate data matrix, or a matrix of the pairwise proximities among the N cases to be clustered. If the data are in raw multivariate form, and include categorical predictors, dummy coding of the category levels may be necessary before computing distances or correlations.

One of the thorny problems in cluster analysis of multivariate data concerns standardization of variables. To illustrate, if we have students in a high-school classroom described by their age, gender (dummy coded as 1 = Female or 0 = Other), and SAT mathematics test score, it usually will not make sense to compute the Euclidean distances among students using these three raw-score variables, because the scale of the SAT score variable will cause it to dominate the other two measures, yielding essentially unidimensional structure in the distances matrix. For this reason, many researchers standardize the variables before inputting the data to k-means or Ward’s method, or before computing a proximity measure. However, this practice can sometimes cause noise to obscure signal. For example, if 48 of 50 students are age 16, but two are 17, standardizing the age variable will cause it to have equal weight with gender and SAT score, even though a one-year difference in age may be trivial or unimportant, and distributed in an arbitrary way. As another example, if the clustering variables are all Likert-scale rating items defined with a 5-point scale, it may not make sense to standardize them, even though some items show a larger variance than others. Simulation studies (Milligan and Cooper, 1988; Steinley, 2006) suggest that standardizing variables by their range is a good generic solution.

A data preparation technique that is fairly widespread in practice, but not always advisable, is to prepare for a cluster analysis by first conducting a principal components analysis (PCA) of the data, then using the scores on the important components (usually defined as those components with eigenvalues ≥ 1) as the input variables to the clustering, rather than the original variables. While

this practice seems to have advantages, such as the convenience of dealing with a smaller number of input variables, and ensuring that those input variables are uncorrelated, it has disadvantages as well. First, the continuous nature of the component scores may obscure cluster-like structure in the data. Second, using factor or component scores may hide, rather than solve, issues surrounding variable selection, weighting and standardization.

Assessing fit and validity of clustering solutions

The quality of a clustering solution can be assessed in any of several ways, and these may vary among methods. One criterion is fit of the cluster model to the data: does the derived solution do a good job of predicting variance in the input variables? For clustering methods such as Ward's method and k-means that take multivariate input, we can assess the RSQ due to the model for each clustering variable as $RSQ = SSB/SST$. The quality of the clustering is often assessed by a MANOVA checking if the clusters differ on the variables used in the clustering, but it should be noted that the p -values associated with such a MANOVA should be taken as merely descriptive, due to the circular logic in performing such a test (we find clusters differing on a set of variables, then test if they differ on these variables). For methods that take a proximity matrix as input, we can calculate model distances for each pair of cases from the derived solution, then correlate these model distances with the input proximities. This is referred to as the "cophenetic correlation" in some clustering references. This correlation squared also gives an estimate of the proportion of variance in the data accounted for by the model. In contrast, Latent Class Clustering models are fit by Maximum Likelihood Estimation, thus likelihood-based model fit statistics such as AIC or BIC can be computed and used.

Stability of the clustering solution is also of interest, because stability indicates a strong cluster structure that emerges regardless of minor changes in the analysis settings or parameters. For a method such as k-means, a given data set can (and should) be fit a large number of times with randomly chosen initial cluster seeds. The percentage of these runs that result in the maximal value of RSQ gives a good indication of the stability of the solution. Cluster stability might also be assessed using a resampling technique such as the jackknife or the bootstrap (e.g., Hennig, 2007).

The validity of a clustering solution can be assessed in a number of ways. First, of course, is the criterion of face validity: the clusters should be interpretable in terms of what is known about the application domain and the data. Also, the clusters should seem internally homogeneous and distinct from one another. Ideally, the clusters should also exhibit external validity, that is, the clusters ought to differ on relevant external criterion variables. For example, a clustering of students based on their patterns of interaction with an online course might reasonably be expected to predict learning outcomes. Thus, it is often informative to present profiles of the derived clusters (say, in a partitioning) not only on the variables used for the clustering, but also for other relevant demographic or outcome variables. MANOVAs or ANOVAs testing for differences in these related variables can often provide useful evidence of external validity.

Illustrative applications of clustering in education

Clustering methods have been applied to a wide variety of data pertaining to education, featuring analyses of the relationships among schools or other educational institutions, classrooms and teachers, curricula, test items, and students, among other entities. Many of these applications have been described in education-focused publications, but relevant work can be found in other literatures, including statistics and various subdisciplines of psychology, such as organizational behavior, cognitive, and clinical/counseling. The highly selective sample of educational applications given below are organized by their area of application within education, moving from the most general types of case or instance (clustering of countries, educational institutions) to the highly specific (clustering of individual students or test items).

Clustering of countries

Large international comparative studies of educational achievement such as Trends in International Mathematics and Science Study (TIMSS) and Program for International Student Assessment (PISA) yield comprehensive databases that offer rich opportunities for secondary data analysis using multivariate methods, including clustering. For example, Olsen and Lie (2011) analyzed 52 science interest items embedded in PISA 2006 to explore 15-year old students' interest in science in 57 countries, in order to ascertain if science interest profiles differ across groups of culturally related countries. They analyzed the correlations among these interest items, first "double-centering" or residualizing the score on each item by subtracting the overall means for that country and that item. They then used average-link hierarchical clustering on these correlations to obtain a dendrogram of countries. The structure of the tree diagram showed a number of culturally related groups of countries. Based on this tree, using measures of cluster distinctiveness, the authors proposed a partition with clusters labeled *Chinese*, *Central/South Asian*, *Ibero-American*, *English*, *Nordic*, *German*, *French*, *Baltic*, and *Slavic*. They conclude that linguistic and other cultural factors seem to influence students' interest in science, with the distinction between scientific issues involving living systems and those addressing physical/technological systems playing a role in producing different profiles of item responses across countries and regions.

In another use of cluster analysis to explore educational differences among countries, Forbes et al. (2020) investigated the relationship between use of inquiry-based instruction and science achievement. Using data from PISA 2015, Forbes et al. first used

Latent Profile Analysis to find clusters of students with different profiles of inquiry-based science teaching within each of $n = 13$ countries selected to represent a range of science teaching practices and student science achievement. They found fundamental differences in the frequency and nature of inquiry-based instruction reported by students associated with the highest and lowest levels of science achievement. They then investigated differences among these countries in the profiles of inquiry-based teaching methods associated with the highest-performing cluster in each country using complete-link hierarchical clustering on the Euclidean distances among profiles. The hierarchical clustering revealed four main clusters of countries, including one cluster that showed low levels of inquiry-based teaching (Bulgaria, Hungary, South Korea) and one that showed overall high levels (Denmark, France). The two intermediate-level clusters were differentiated largely by the reported amount of classroom debate and student testing of their own ideas.

Clustering of educational institutions, classrooms, and teachers

Cluster analysis methods have been used successfully to study diversity in educational institutions, classrooms, and teachers. In a classic study by Moos (1978), student perceptions of classroom climate were used to analyze 200 junior high and high school classrooms. The classroom climate instrument used yielded nine subscales. The intraclass correlations for each classroom were used in a hierarchical cluster analysis, which yielded five groups of classrooms (with four classrooms left unclassified): control oriented, innovation oriented, affiliation oriented, task oriented and competition oriented. External validation of the clusters showed differences in student satisfaction and mood, and in teacher satisfaction.

Dorman et al. (2006) studied classroom environments, including incorporation of technology, in a sample of 286 secondary-school classrooms in Australia, using student responses to an instrument assessing 10 classroom environment dimensions: student cohesiveness, teacher support, involvement, task orientation, investigation, cooperation, equity, differentiation, computer usage and young adult ethos. A hierarchical cluster analysis (not further specified) of the student responses was used to find a partition into five groups of classrooms, which were labeled *exemplary*, *safe and conservative*, *non-technological teacher-centered*, *contested technological*, and *contested non-technological*.

A study by de Kruif et al. (2000) investigated patterns of teachers' interaction behaviors in early childhood classrooms. Sixty-three pre-K teachers were rated on their use of eight interaction behaviors, including such behaviors as redirecting, acknowledging, praising, etc. The authors used hierarchical clustering (not further specified) followed by k-means clustering to obtain four clusters of teacher interaction styles, labeled average, elaborating, controlling, and nonelaborative. Validation of the clusters by external variables indicated that the clusters were differentiated by teachers' education, scores on a caregiver sensitivity measure, classroom quality, group child engagement, and licensing level of the pre-K center.

Clustering of students

Clustering methods seem ideally suited to studying student attitudes, beliefs, and achievement, because these methods seek to describe and find common patterns in diversity. In particular, students may be grouped according to their similarity on demographic, social, or cognitive attributes, but often are classified based on their academic attainment or other aspects of their learning history.

As an example of clustering for the purposes of theory development or confirmation, Speece et al. (1985) used hierarchical clustering to identify seven distinct behavioral subtypes of children identified by their schools as learning-disabled. The clustering was based on subscale scores on a teacher rating of classroom behaviors. The obtained subtypes were stable and reliable, and the subtype profiles on the clustering variables differed from a sample of children without identified learning disabilities. The subtypes differed significantly on independent observational measures and on ratings by special education teachers, but not on achievement or intelligence. Interpretation of the subtypes confirmed a multiple-syndrome view of learning disabilities.

A study by Rowley (2000) used hierarchical clustering to explore African American students' beliefs about the value of getting a good education. Using Ward's method, five clusters of African American college students ($N = 126$) were identified with differing profiles on two measures of idealistic and context-specific educational utility and on grades. These clusters were then related to profiles on a racial ideology/Black identity scale. The results indicated that African American students hold a variety of perspectives about the value of education, and that certain types of beliefs naturally occur in students with certain academic performance records.

In a study of student motivation and self-regulated learning motivated by self-determination theory, Ng et al. (2016) collected data from 782 students in science courses from eight secondary schools in Singapore. Based on a questionnaire measuring motivational beliefs and learning strategies, they used Ward's method for hierarchical clustering to derive four clusters of students, then confirmed these clusters using k-means. The clusters differed significantly (by a MANOVA test) not only on the motivational beliefs and strategies variables used in the clustering, but also on the scales of a questionnaire based on self-determination theory, and on term grades in science.

Clustering has been frequently employed within the educational data mining (EDM) community as a means of finding structure in large data sets, where it is sometimes referred to as a technique for "unsupervised learning" (Romera and Ventura, 2007; Dutt et al., 2017). For example, Rodrigo et al. (2008) analyzed the logs of student interaction with Aplusix, an intelligent tutoring system for algebra. Based on a k-means analysis, they determined that students fell into two primary groups: one with a more collaborative interaction style and one with a more solitary style of work. In another study, Trivedi et al. (2011) clustered middle school students based on their work with the ASSISTments tutoring system, using both scores on problems and certain "dynamic" measures of

interaction with the system, including number of problems done, percent correct on the help questions, average time spent per item, average number of attempts per item, and average numbers of hints per item. Trivedi et al. used k-means clustering, with 200 random-seed starts, for the cluster analyses, and evaluated the results for $k = 2-7$ cluster solutions. They then developed separate prediction models for each cluster, using the above variables (plus the “static” measure of average score on the main problems) to predict the criterion of test score on the MCAS arithmetic subtest, a statewide Massachusetts test. These cluster-specific prediction models, and ensemble combination of their predictions, improve prediction of the criterion achievement scores.

Clustering of educational test items

When the achievement of students is measured, and item-level data is retained, the resulting persons $\times$ items matrix of scores may be fruitfully analyzed by cluster analysis. While cluster analysis of individuals based on their test performance has a long history (e.g., Thorndike, 1953), cluster analyses of the correlations among test items is relatively rare. This may be due in part to the traditional use of dimensional models such as PCA or factor analysis to analyze the correlations among items. But as mentioned above, FA or PCA is often employed to find homogeneous subsets of items that might be considered as subscales, a goal that can be accomplished more directly with clustering methods. A few such analyses (e.g., Revelle, 1979) are found in the literature, with some studies finding better model fit for hierarchical clustering models than for the traditional dimensional models (Beller, 1990).

In an application to diagnostic testing, Corter (1995) analyzed correlations from a diagnostic test of mixed-fraction subtraction skills, applying a hierarchical clustering method (additive trees) and the EXTREE method for finding overlapping clusters, to discover subsets of items that correspond to necessary subskills or “attributes” of the Q-matrix used in many diagnostic measurement models. Because the attributes of a Q matrix are not necessarily hierarchically structured (though they may be for some tests), the use of overlapping cluster methods seems most appropriate for this purpose. Recent work using clustering in the context of diagnostic classification models (DCMs) has returned to the problem of classifying examinees rather than items, because a DCM can be thought of as a method for sorting examinees into latent test profiles, essentially an LCA problem. Chiu et al. (2009) explored the use of similarity-based partitioning and hierarchical clustering methods as an alternative robust technique for accomplishing this diagnostic classification of examinees. They proved that for educational test data meeting certain assumptions, the probability that hierarchical cluster analysis assigns examinees to their true proficiency classes approaches 1 as the number of test items increases.

Clustering of learner knowledge

A study that illustrates the use of clustering as an unsupervised learning method employed overlapping clustering to discover structure in the arithmetic knowledge that mathematics learners possess about the numbers 0 through 9 (Shepard et al., 1975). Shepard et al. asked college students (expert-level learners) to rate the similarity of these numbers, presented as written numerals but judged as abstract concepts. The six-cluster additive clustering solution for these similarity judgments (obtained using the ADCLUS program, Shepard and Arabie, 1979) is shown in Fig. 5. Here, the clusters are depicted as loops enclosing the set of numbers associated with that cluster. The positions of the points representing the numbers 0–9 are arbitrary for the clustering, but are positioned here in a way that is convenient for the loops representation, as determined by a prior multidimensional scaling analysis.

The solution features highly interpretable clusters. One cluster picks out 0 and 1, the additive and multiplicative identities, another is comprised of the odd primes, and the powers and multiples of 2 and of 3 define the other four clusters. This overlapping cluster analysis demonstrates that student knowledge of the mathematical properties of the numbers can be inferred from a cluster analysis of the students’ similarity judgments.

Fig. 5 Six-cluster additive clustering (ADCLUS) solution reported by Shepard et al. (1975) for the similarity ratings among the numbers 0–9. Cluster interpretations are given within each loop.

Conclusions

Techniques for cluster analysis are useful exploratory techniques for data reduction and data exploration. As the applications in this article suggest, they can also be useful for theory discovery and theory confirmation in educational research. A broad and deep understanding of cluster analysis models and techniques is helpful in ensuring that these methods are used appropriately, and that the results of such analyses are correctly interpreted.

One fundamental issue is the choice of an appropriate clustering model/method, a choice that is seldom explicitly discussed. In the educational literature, techniques for partitioning and for hierarchical clustering are widely used. However, as noted, sometimes hierarchical clustering techniques are used merely as a quick and convenient way of identifying partitions. Techniques for fitting overlapping sets of clusters have been less widely available, and arguably underused in educational research. However, as these techniques become better known and the software for fitting them become more widely available, they will perhaps become more popular.

Other issues that researchers should be aware of when using cluster analysis include proper preparation of the data, choice of software, and implementation parameters for the analysis. While best practices have been briefly outlined here, these issues have been more deeply explored elsewhere in the methodological literature. Cluster analysis techniques are recommended as useful technique in educational research, useful (and promising) enough to justify these continuing development efforts.

Introduction

A statistical model can be called a latent class (LC) or mixture model if it assumes that some of its parameters differ across unobserved subgroups, latent classes, or mixture components. This rather general idea has several seemingly unrelated applications, the most important of which are clustering, scaling, density estimation, and random-effects modeling. It should be noted that in applied fields the terms LC model and mixture model are often used interchangeably, which is also what I will do here. In the more technical statistical literature on mixture modeling, the term LC analysis is reserved for a specific type of mixture model, that is, a mixture model for a set of categorical items (for the classical LC model).

LC analysis was introduced in 1950 by Lazarsfeld as a tool for building typologies (or clustering) based on dichotomous observed variables. More than 20 years later, Goodman (1974) made this model applicable in practice by developing an algorithm for obtaining maximum likelihood estimates of the model parameters, as well as proposed extensions for polytomous manifest variables and did important work on the issue of model identification. Many important extensions of this classical LC model have been proposed since then, such as models containing explanatory variables (Dayton and Macready, 1988), models that relax the local independence assumption (Hagenaars, 1988), constrained models similar to IRT models (Lindsay et al., 1991; Heinen, 1996), models with multiple latent variables (Magidson and Vermunt, 2001), models for longitudinal data (Van de Pol and Langeheine, 1990; Collins and Lanza, 2010), models for multilevel data (Vermunt, 2003, 2010b), three-step LC analysis (Bolck et al., 2004; Vermunt, 2010a), and LC tree models (Van den Bergh et al., 2018).

Whereas the classical LC model and its extensions are conceived primarily as a clustering and scaling tool for categorical data analysis, LC and finite mixture models can be useful in several other areas as well. One of these is as a probabilistic cluster analysis tool for continuous observed variables, an approach that offers many advantages over traditional cluster techniques such as K-means clustering (Wolfe, 1970; McLachlan and Peel, 2000; Vermunt and Magidson, 2002). Another application area is dealing with unobserved heterogeneity, as happens in mixture regression analysis of multilevel or repeated measurement data (Wedel and De Sarbo, 1994; Vermunt and Van Dijk, 2001).

The remainder of this article is organized as follows. After introducing the simplest type of LC models, I discuss various restricted LC models as well as models with explanatory variables. Next, I give an overview of other types of LC and mixture models, which includes various recently proposed extensions. The remaining sections focus on parameter estimation, model selection, and software. An annotated list of further reading is provided at the end of the chapter.

Simple LC and mixture models

LC analysis is typically used as a tool for analyzing multivariate response data; that is, data consisting of several dependent variables, response variables, or items. We will denote the response of subject i on dependent variable j by y_{ij} , and the number of dependent variables by J . The full response vector of a subject is denoted by y_i . To make things more concrete, Table 1 presents a small illustrative data set consisting of three dichotomous responses, y_{i1} , y_{i2} , and y_{i3} ($0 = \text{incorrect}$; $1 = \text{correct}$). This is a subset of items from a mathematics test administered to 2156 children; that is, the first three items (out of a total of 18) from the Latent GOLD demo data file “cito.dat.” The column “Frequency” contains the observed frequency count for each of the eight possible answer patterns.

Table 1 Small data set with three dichotomous responses.

y_{i1}	y_{i2}	y_{i3}	Frequency	$f(\mathbf{y}_i)$	$f(\mathbf{y}_i v_i = 1)$	$f(\mathbf{y}_i v_i = 2)$	$f(v_i = 1 \mathbf{y}_i)$	$f(v_i = 2 \mathbf{y}_i)$	Modal
0	0	0	239	0.111	0.004	0.272	0.020	0.980	2
0	0	1	101	0.047	0.010	0.102	0.128	0.872	2
0	1	0	283	0.131	0.038	0.271	0.175	0.825	2
0	1	1	222	0.103	0.104	0.102	0.605	0.395	1
1	0	0	105	0.049	0.020	0.092	0.248	0.753	2
1	0	1	100	0.046	0.054	0.035	0.703	0.297	1
1	1	0	348	0.161	0.208	0.091	0.774	0.226	1
1	1	1	758	0.352	0.562	0.034	0.961	0.039	1

Note: These are the first three items (out of a total of 18) from the Latent GOLD demo data file called "cito.dat."

In addition to the J observed dependent variables, a LC model contains a discrete latent variable. We will denote a subject's unobserved score on this latent variable by v_i , the number of LCs by C , and a particular class by c , where $c = 1, 2, \dots, C$. The aim of a LC analysis of the data set in **Table 1** could be to classify pupils into two groups, masters and non-masters, which differ with respect to the probability of answering the test items correctly. The results obtained with a 2-class model will be used to illustrate the various components of a LC model.

LC analysis defines a model for $f(\mathbf{y}_i)$, the probability density of the multivariate response vector $\mathbf{y}_i$. In the above example this is the probability of answering the items according to one of the eight possible response patterns, for example, of answering the first two items correctly and the last one incorrectly ($y_{i1} = 1, y_{i2} = 1, y_{i3} = 0$), which as can be seen in **Table 1** equals 0.161 for the estimated 2-class model. The assumption underlying any type of LC or mixture model is that the density $f(\mathbf{y}_i)$ is a weighted average (or mixture) of the C class-specific densities $f(\mathbf{y}_i|v_i = c)$. This is expressed mathematically as follows:

$$f(\mathbf{y}_i) = \sum_{c=1}^C P(v_i = c) f(\mathbf{y}_i|v_i = c) \quad (1)$$

Here, $P(v_i = c)$ denotes the probability that a subject belongs to LC c . For our small empirical example, the estimates of these (prior) class membership probabilities are 0.601 and 0.399 for class 1 and 2, respectively (see **Table 2**). The assumed mechanism by **Eq. (1)** is that each individual belongs to one of C exhaustive and mutually exclusive classes with probability $P(v_i = c)$ and that given membership of LC c an individual provides responses according to the probability density associated to this class. **Table 1** shows the estimated values of $f(\mathbf{y}_i|v_i = 1)$ and $f(\mathbf{y}_i|v_i = 2)$ for our data sets. As can be seen, LC 1 has higher probabilities for the response patterns with 2 or 3 correctly answered items, whereas LC 2 has higher probabilities for the response patterns with 0 or 1 item correct.

The classical LC model combines the assumption of **Eq. (1)** shared by all mixture models with the assumption of local independence. Local independence means that the J responses are mutually independent given a subject's class membership. It can be expressed as follows:

$$f(\mathbf{y}_i|v_i = c) = \prod_{j=1}^J f(y_{ij}|v_i = c) \quad (2)$$

Independence implies that the joint density $f(\mathbf{y}_i|v_i = c)$ is obtained as a product of the J item-specific densities $f(y_{ij}|v_i = c)$. In our example, $f(y_{ij} = 1|v_i = c)$, is the class-specific probability of giving a correct answer to item j . As reported in **Table 2**, for a subject belonging to the first LC, these equal 0.844, 0.912, and 0.730 for items 1, 2 and 3, respectively. The local independence assumption implies, for example, that the probability of answering the first two items correctly and the last one incorrectly for someone in LC 1 equals $0.844 \times 0.912 \times (1 - 0.730) = 0.208$. Note that the local independence assumption is also used in other types of latent variables models, such as in factor analysis and IRT modeling, and is thus not specific for LC analysis.

Combining the two basic **Eqs. (1) and (2)** yields the following model for $f(\mathbf{y}_i)$:

Table 2 Parameters (class proportions and probability of a correct answer) obtained with a 2-class model for data in **Table 1**.

	$c = 1$	$c = 2$
$P(v_i = c)$	0.601	0.399
$\pi_{11c} = P(y_{i1} = 1 v_i = c)$	0.844	0.252
$\pi_{21c} = P(y_{i2} = 1 v_i = c)$	0.912	0.499
$\pi_{31c} = P(y_{i3} = 1 v_i = c)$	0.730	0.273

$$f(\mathbf{y}_i) = \sum_{c=1}^C P(v_i = c) \prod_{j=1}^J f(y_{ij} | v_i = c) \quad (3)$$

To complete the model specification, we need to define the form of the conditional densities $f(y_{ij} | v_i = c)$. In the classical LC model for categorical items these are multinomial probability densities; that is,

$$f(y_{ij} | v_i = c) = \prod_{r=0}^{R_j-1} \pi_{jrc}^{y_{ijr}^*}$$

where R_j is the number of categories of item j , $0 \leq y_{ij} \leq R_j - 1$, and $y_{ijr}^* = 1$ if $y_{ij} = r$ and 0 otherwise. Note this is a slightly complicated, but mathematically elegant, way to express that someone in LC c has a probability equal to $\pi_{jrc} = P(y_{ij} = r | v_i = c)$ of giving response r to item j . In the special case of a dichotomous response, the multinomial distribution reduces to the Bernoulli distribution with success probability $\pi_{jc} = \pi_{j1c} = P(y_{ij} = 1 | v_i = c)$. **Table 2** presents these probabilities for our small example.

It is important to note that LC models can not only be used with categorical responses, but also with continuous responses and counts. The density $f(y_{ij} | v_i = c)$ could be a binomial, Poisson, or negative binomial distribution for counts, and a normal or gamma distribution for continuous responses. The mixture model for continuous response variables is sometimes referred to as the latent profile model. The parameters of this model are the class proportions and class-specific item means and variances (μ_{jc} and σ_{jc}^2).

By comparing the J sets of item parameters across classes, one can name the classes. The parameter estimates presented in **Table 2** show that the first class can be named the masters because pupils belonging to that class have much higher probabilities of answering the test items correctly than pupils belonging to the second non-masters class.

Similar to cluster analysis, one of the purposes of LC analysis might be to assign individuals to LCs. The probability of belonging to LC c given responses $\mathbf{y}_i$ —often referred to as posterior membership probability—can be obtained by the Bayes rule:

$$P(v_i = c | \mathbf{y}_i) = \frac{P(v_i = c) f(\mathbf{y}_i | v_i = c)}{f(\mathbf{y}_i)} \quad (4)$$

Table 1 reports $P(v_i = c | \mathbf{y}_i)$ for each answer pattern. For example, $P(v_i = 1 | \mathbf{y}_i)$ equals 0.774 for the (1,1,0) pattern, which is obtained as $0.601 \times 0.208 / 0.161$. The most common classification rule is modal assignment, which amounts to assigning each individual to the LC with the highest $f(v_i = c | \mathbf{y}_i)$. The last column of **Table 1** reporting the modal assignments shows that pupils with at least 2 correct answers are assigned to class 1 and the others to class 2.

In the introduction we stated that mixture models are statistical models in which parameters are assumed to differ across LCs. But what is the statistical model used in the simple LC models discussed so far? It is the independence model: we assume responses to be independent, with different parameter values for each class. Depending on the scale type of the response variables, these parameters are Bernoulli probabilities, multinomial probabilities, normal means and variances, Poisson rates, etc.

Generalized linear models for item probabilities/means

Haberman (1979) showed that the LC model for categorical response variables can also be specified as a log-linear model for an expanded table, including the latent variable v_i as an additional dimension. Using such a log-linear specification is equivalent to parameterizing the response probability for item j as follows:

$$\log\left(\frac{\pi_{jrc}}{\pi_{j0c}}\right) = \log\left(\frac{P(y_{ij} = r | v_i = c)}{P(y_{ij} = 0 | v_i = c)}\right) = \alpha_{jr} + \beta_{jcr} \quad (5)$$

for $1 \leq r \leq R_j - 1$; that is, as a multinomial logistic regression model with intercepts α_{jr} and slopes β_{jcr} (note that we use the first item category, $r = 0$, as baseline). One identification constraint needs to be imposed, for example, $\beta_{j1r} = 0$ (the parameters for class 1 are fixed to 0) or $\alpha_{jr} = 0$ (intercepts are fixed to 0).

For dichotomous responses and binomial counts, the regression model could be a binary logit or probit model, for Poisson counts a log-linear model, and for continuous responses a standard linear model. These are generalized linear models (GLMs) of the form

$$g[E(y_{ij} | v_i = c)] = \alpha_j + \beta_{jc} \quad (6)$$

where $g[\cdot]$ is the link function transforming the expected value of y_{ij} to the linear term. For ordinal polytomous variables, one may use an ordinal regression model, such as an adjacent-category or cumulative logit model. These are models that restrict the item response probabilities π_{jrc} .

Some restricted models for categorical items

Many interesting types of restricted LC models for categorical items have been proposed which involve imposing (linear) constraints on either the conditional probabilities π_{jrc} or the logit coefficients of Eq. (5). One of these are probabilistic Guttman scaling models for dichotomous responses, which are LC models with $C = J + 1$ classes, one for each possible total score. The idea is that apart from measurement error, class c should provide a positive (correct) answer to the $c-1$ easiest items and a negative (incorrect) answer to the remaining $J-(c-1)$ items. The various types of probabilistic Guttman models differ in constraints they impose on the measurement error. The simplest and most restricted model is the Proctor (1970) model. Table 3 presents the parameter estimates obtained when fitting the Proctor model to the data set in Table 1. As can be seen, the probability of a correct response is either 0.833 or $0.167 = 1 - 0.833$. The measurement error—or the probability of giving a response which is not in agreement with the class—is estimated to be equal to 0.167. Whereas the Proctor model assumes that the measurement error is constant across items and classes, less restricted models can be defined which allow the error probabilities to differ across items, classes, or both (see, e.g., Dayton, 1999). Note that these equality constraints on the error probabilities can also be defined using linear constraints on the logit parameters: $\alpha_{j1} = 0$ and $\beta_{j1c} = -\beta^*$ for $c \leq j$ and $\beta_{jc} = \beta^*$ otherwise.

Croon (1990) proposed a restricted LC model that similar to non-parametric IRT (Sijtsma and Molenaar, 2002) assumes monotonic item response functions; that is, $\pi_{j1c} \leq \pi_{j1,c+1}$, or, equivalently, $\beta_{j1c} \leq \beta_{j1,c+1}$. A more restricted version, in which not only classes but also items are ordered, is obtained by imposing the additional set of restriction $\pi_{j+11c} \leq \pi_{j1c}$; that is, by assuming double monotony. Vermunt (2001) discussed various generalizations of these models.

Various authors described the connection between restricted LC analysis and parametric IRT modeling (see, for example, Heinen, 1996; Lindsay et al., 1991); that is, IRT models with a discrete specification of the distribution of the underlying trait or ability can be defined as LC models with restrictions on the logistic parameters. The key restriction is $\beta_{jrc} = \beta_{jr}^* \cdot \theta_c$ for nominal items and $\beta_{jrc} = \beta_j^* \cdot r \cdot \theta_c$ for ordinal items, where the θ_c are LC locations representing the C possible values of the discretized latent trait. These locations may be fixed a priori, for example, at $-2, -1, 0, 1$, and 2 in the case of $C = 5$, but may also be treated as free parameters to be estimated. Depending on whether the items are dichotomous, ordinal, or nominal, this yields a 2-parameter logistic, generalized partial credit, or nominal response model. Further restrictions involve equating β_j^* across items, yielding Rasch and partial credit models, and imposing across category and across item restrictions on α_{jr} parameters as in rating scale models for ordinal items.

Models with explanatory variables

The most important extension of the LC models discussed so far is the possibility to include explanatory variables (covariates) affecting the responses (Wedel and DeSarbo, 1994) or the class memberships (Dayton and Macready, 1988). Denoting the vector with explanatory variables for subject i by $\mathbf{x}_i$, the LC model of interest can be formulated as follows:

$$f(\mathbf{y}_i | \mathbf{x}_i) = \sum_{c=1}^C P(v_i = c | \mathbf{x}_i) \prod_{j=1}^{J_i} f(y_{ij} | v_i = c, \mathbf{x}_{ij}) \quad (7)$$

The main difference compared to the model defined in Eq. (3) is that now we have a model for $f(\mathbf{y}_i | \mathbf{x}_i)$ —the conditional density of $\mathbf{y}_i$ given $\mathbf{x}_i$.

Similar to the regression models for the response variables introduced in Eqs. (5) and (6), one can define a mixture regression model with explanatory variables; i.e.,

$$g\left[E(y_{ij} | v_i = c, \mathbf{x}_{ij})\right] = \alpha_c + \sum_{p=1}^P \beta_{pc} \mathbf{x}_{ijp} \quad (8)$$

As before, y_{ij} may refer to the response on item j by pupil i , in which case the explanatory variables in a long (two-level) format data file will consist of a design matrix defining the item parameters. For our small example with 3 items, the data file will contain 3 records per person—one per item. Each record has 4 columns with the first column containing an identifier variable linking the records, the second column indicating the response to a single item, and 2 additional columns for dummy-coded predictors to

Table 3 Parameters (class proportions and probability of a correct answer) obtained with Proctor model for data in Table 1.

	$c = 1$	$c = 2$	$c = 3$	$c = 4$
$P(v_i = c)$	0.160	0.155	0.126	0.559
$\pi_{21c} = P(y_{12} = 1 v_i = c)$	0.167	0.833	0.833	0.833
$\pi_{11c} = P(y_{11} = 1 v_i = c)$	0.167	0.167	0.833	0.833
$\pi_{31c} = P(y_{13} = 1 v_i = c)$	0.167	0.167	0.167	0.833

indicate which item the response is for. Taking the third item as the reference item, the first predictor takes on the value 1 for a record containing the first item response and 0 for the other records, and the second predictor equals 1 for the second response and 0 for the other two responses.

However, the model in Eq. (8) can also be used for many other purposes. In fact, it is a model for analyzing two-level data sets, where regression parameters are allowed to differ across LCs (of higher-level units). For example, γ_{ij} could be the test score of pupil j belonging to school i , and $\mathbf{x}_{ij}$ a set of pupil characteristics (e.g., IQ). A mixture regression model would identify LCs of schools with different intercepts and different effects of child characteristics on the test scores. Another possible application is in the analysis of longitudinal data, where j is a time point for subject i , and where vector $\mathbf{x}_{ij}$ contains time variables. This yields a LC growth model in which subjects are grouped based on their developmental trajectories (Vermunt, 2007). A fourth possible application is in experiments in which subjects are observed in multiple conditions, such as in conjoint studies. The mixture regression model can be used to group subjects based on their reactions on the experimental conditions. In fact, in each of these application types, the LC model is used as a random-coefficient model without parametric assumptions about the distribution of the random effects (Aitkin, 1999; Vermunt and Van Dijk, 2001).

As shown in Eq. (7), an individual's class membership may also be predicted using covariates. This is achieved by defining a multinomial logistic regression model for $P(v_i = c | \mathbf{x}_i)$:

$$\log \frac{P(v_i = c | \mathbf{x}_i)}{P(v_i = 1 | \mathbf{x}_i)} = \gamma_{0c} + \sum_{q=1}^Q \gamma_{pc} x_{iq}$$

Strongly related are multiple-group LC models (Hagenaars and McCutcheon, 2002; Magidson and Vermunt, 2004; Kankaraš et al., 2010). These can be defined by using the grouping variable as a nominal explanatory in the model.

Three-step latent class analysis

Rather than including covariates directly within the estimated LC model, one may also use the following type of three-step approach:

1. Perform model selection and estimation in the usual way, thus without the inclusion of covariates;
2. Obtain class assignments w using the selected model from step 1, as explained in Eq. (4);
3. Perform subsequent analyses with covariates or other types of external variables using the class assignments w of step 2.

Although this stepwise approach of separating the LC analysis from the analyses one would like to do after the latent classes are constructed is very practical and intuitive, it is also problematic. More specifically, as a result of the classification errors introduced in step 2, it yields underestimated associations between external variables and latent classes. The larger the classification errors, the larger the bias in the estimates of these associations.

However, building upon the work by Bolck et al. (2004), Vermunt (2010a) proposed a solution to this problem. He showed how to perform a valid step-3 analysis by adjusting for the classification errors introduced in step 2. Basically, a new LC model is estimated in which the class assignments w are used as the single indicator with known conditional response probabilities $P(w | v_i = c)$. This adjusted step-3 analysis can not only be used with covariates predicting class membership (via a logistic model), but also for investigating how classes differ with respect to a distal outcome variable (Bakk et al., 2013). Bakk and Vermunt (2016) recommended using the more robust BCH adjustment method for continuous distal outcomes (dependent variables), while for covariates and categorical distal outcomes the maximum likelihood (ML) approach is preferred.

Extensions

The most common model-fitting strategy in LC analysis is to increase the number of classes until the local independence assumption holds. This may, however, yield solutions which are difficult to interpret. One alternative approach is to relax the local independence assumption by allowing for associations between particular item pairs. Hagenaars (1988) showed how to define LC models with local dependencies for categorical responses. With continuous responses this is easily achieved by using multivariate instead of univariate normal distributions for locally dependent items (see, e.g., McLachlan and Peel, 2000; Vermunt and Magidson, 2002).

Another alternative strategy involves increasing the number of discrete latent variables instead of the number of LCs, which is especially useful if the items measure several dimensions, such as different math subskills. This so-called discrete factor modeling approach (Magidson and Vermunt, 2001) is a special case of the path modeling approach for discrete latent variables developed by Hagenaars (1990), Vermunt (1997). Many other interesting models can be defined within this framework, such as latent Markov (or transition) models for the analysis of longitudinal data (Collins and Lanza, 2010; Van de Pol and Langeheine, 1990; Vermunt et al., 2008) and LC models for cognitive diagnosis (De la Torre and Douglas, 2004).

Another interesting extension is the LC tree approach (Van den Bergh et al., 2018), in which after starting with a small number of classes at the root of the tree, a hierarchical structure of mutually linked classes is obtained by sequentially splitting classes into two

subclasses as long as the model fit improves. This approach, which is similar to (divisive) hierarchical clustering, can also be combined with mixture growth modeling and three-step LC analysis.

Various types of models have been developed that contain both discrete and continuous latent variables, examples of which include mixture factor models (Yung, 1997; McLachlan and Peel, 2000), mixture structural equation models (Dolan and Van der Maas, 1997), and mixture IRT models (Rost, 1990). Recently, extensions of mixture factor modeling have been proposed for detecting sources of measurement non-invariance in intensive longitudinal data, multiple-group data for many groups, and multi-level data (De Roover et al., 2017, 2022; Vogelsmeier et al., 2019).

Another important extension is the multilevel LC model (Vermunt, 2003, 2010b). One of its variants is a model with discrete latent variables at multiple levels of a hierarchical structure: e.g., children belong to LCs with different performances on a set of test items, and schools belong to LCs with different distributions of children across the child-level performance classes. Multilevel LC models can be used for the analysis of two-level multivariate and three-level univariate response data.

Lanza et al. (2013), Clouth et al. (2022) showed how to combine LC analysis with tools for causal inference in observational (non-experimental) studies. More specifically, Lanza et al. (2013) illustrated the use of inverse propensity weighting and matching based on propensity scores to determine the effect of a treatment on class membership. As an alternative, Clouth et al. (2022) proposed using a three-step LC approach with inverse propensity weighting.

Maximum likelihood estimation

The parameters of LC models are typically estimated by means of maximum likelihood (ML). The log-likelihood function that is maximized is based on the probability densities defined in Eqs. (1), (2), and (3); that is,

$$\ln L = \sum_{i=1}^N \ln f(\mathbf{y}_i)$$

with categorical responses one will typically group the data and construct a frequency table as we did in Table 1. The log-likelihood function for grouped data equals

$$\ln L = \sum_{k=1}^K n_k \ln f(\mathbf{y}_k)$$

where k is a data pattern, K the number of different data patterns and n_k the cell count corresponding to data pattern k . Notice that only nonzero observed cell entries contribute to the log-likelihood function, a feature that is exploited by several more efficient LC software packages that have been developed within the past few years (see the Software section for more discussion of these packages).

One of the problems in the estimation of LC models for discrete y_{ij} is that model parameters may be nonidentified, even if the number of degrees of freedom—the number of independent cells in the J -way cross-tabulation minus the number of free parameters—is larger or equal to zero. Nonidentification means that different sets of parameter values yield the same maximum of the log-likelihood function or, worded differently, that there is no unique set of parameter estimates. The formal identification check is via the Jacobian matrix (matrix of first derivatives of $f(\mathbf{y}_i)$), which should be column full rank. Another option is to estimate the model of interest with different sets of starting values. Except for local solutions (see below), an identified model gives the same final estimates for each set of the starting values.

Although there are no general rules with respect to the identification of LC models, it is possible to provide certain minimal requirements and point to possible pitfalls. For an unrestricted LC analysis, one needs at least three responses (y_{ij} 's) per individual, but if these are dichotomous, no more than two LCs can be identified. One has to be careful with four dichotomous response variables, in which case the unrestricted three-class model is not identified, even though it has a positive number of degrees of freedom. With five dichotomous items, however, even a five-class model is identified. Usually, it is possible to achieve identification by constraining certain model parameters.

A second problem associated with the estimation of LC models is the presence of local maxima. The log-likelihood function of a LC model is not always concave, which means that hill-climbing algorithms may converge to a different maximum depending on the starting values. Usually, we are looking for the global maximum. The best way to proceed is, therefore, to estimate the model with different sets of random starting values. Typically, several sets converge to the same highest log-likelihood value, which can then be assumed to be the ML solution. Current LC analysis software packages have automated the use of multiple sets of random starting values to reduce the probability of getting a local solution.

Another problem in LC modeling is the occurrence of boundary solutions, which are probabilities equal to 0 (or 1) or logit parameters equal to minus (or plus) infinity. These may cause numerical problems in the estimation algorithms, occurrence of local solutions, and complications in the computation of standard errors and number of degrees of freedom of the goodness-of-fit tests. Boundary solutions can be prevented by imposing constraints or by taking into account other kinds of prior information on the model parameters.

The most popular methods for solving the ML estimation problem are the expectation-maximization (EM) and Newton-Raphson (NR) algorithms. EM is a very stable iterative method for ML estimation with incomplete data. NR is a faster procedure that, however, needs good starting values to converge. The latter method makes use of the matrix of second-order derivatives of the log-likelihood function, which is also needed for obtaining standard errors of the model parameters.

Model selection issues

The goodness-of-fit of LC models for categorical responses can be tested using Pearson and likelihood-ratio chi-squared tests. The latter is defined as

$$L^2 = 2 \sum_{k=1}^K n_k \ln \frac{n_k}{N \cdot f(y_k)}$$

As in log-linear analysis, the number of degrees of freedom (df) equals the number of cells in the frequency table minus 1, minus the number of independent parameters. In an unrestricted LC model,

$$df = \prod_{j=1}^J R_j - C \cdot \left[1 + \sum_{j=1}^J (R_j - 1) \right]$$

Although it is no problem to estimate LC models with 10, 20, or 50 indicators, in such cases, the frequency table may become very sparse and, as a result, asymptotic p -values can no longer be trusted. An elegant but somewhat time-consuming solution to this problem is to estimate the p -values by parametric bootstrapping. Another option is to assess model fit in lower-order marginal tables (e.g., in the two-way marginal tables). Magidson and Vermunt (2004) refer to Pearson chi-squared statistics in two-way tables as bivariate residuals (or BVRs).

Even though models with C and $C + 1$ are nested, one cannot test them against each other using a standard likelihood-ratio ($-2 \ln L$ difference) test because it does not have an asymptotic chi-squared distribution. A solution to this problem is to approximate its sampling distribution using bootstrapping. But since this method is computationally demanding, usually alternative methods are required for comparing models with different numbers of classes. One popular method is the use of information criteria, such as the Bayesian Information Criterion (BIC), the Akaike Information Criterion (AIC), and the AIC3 (a variant of the AIC which uses a penalty of 3 instead of 2 per parameter), where smaller values indicate better model fit.

Usually, we are not only interested in goodness-of-fit but also in the performance of the modal classification rule (see Eq. 4). The estimated proportion of classification errors under modal classification equals

$$E = \sum_{i=1}^N \frac{1}{N} \{1 - \max[P(v_i = c | y_i)]\}$$

This number can be compared to the proportion of classification errors based on the unconditional probabilities $P(v_i = c)$, yielding a reduction of errors measure

$$\lambda = 1 - \frac{E}{1 - \max[P(v_i = c)]}$$

The closer this nominal R^2 -type measure is to 1, the better the classification performance of a model. Other types of classification error reduction measures have been proposed based on entropy or qualitative variance (Collins and Lanza, 2010; Vermunt and Magidson, 2016).

To illustrate the use of model selection statistics for deciding about the number of classes, Table 4 presents the results for 1- to 6-class models estimated with the "cito.dat" data set using all 18 items, where p -values for the goodness-of-test and the likelihood-

Table 4 Fit measures for the LC models estimated using all 18 items of the "cito.dat" data set.

Model	BIC	AIC	AIC3	L^2	Bootstrap p -value L^2	Largest BVR	$-2 \ln L$ difference	Bootstrap p -value $-2 \ln L$ difference	Entropy R^2
1 Class	44,667.15	44,564.98	44,582.98	15,115.33	0.00	213.86			
2 Classes	41,055.03	40,845.02	40,882.02	11,357.36	0.01	43.34	3757.96	0.00	0.80
3 Classes	40,779.08	40,461.22	40,517.22	10,935.57	0.38	11.89	421.79	0.00	0.69
4 Classes	40,830.76	40,405.06	40,480.06	10,841.40	0.41	6.35	94.17	0.00	0.61
5 Classes	40,929.23	40,395.69	40,489.69	10,794.04	0.37	5.74	47.37	0.07	0.60
6 Classes	41,029.75	40,388.36	40,501.36	10,748.70	0.34	5.92	45.33	0.12	0.59

Note: The selected model is printed in bold. BIC, AIC, and AIC3 select the model with the lowest value, L^2 the simplest model with a non-significant value, largest BVR the simplest model showing a large drop compared to the previous model, and $-2 \ln L$ difference the most complex model with a significant value. Entropy R^2 should not be used for model selection.

ratio test were obtained using bootstrapping (with 500 replications). The simplest model with a non-significant L^2 goodness-of-fit value and moreover with the lowest BIC is the 3-class model, and should thus be selected according to these two statistics. The 4-class model would be selected based on the AIC3, the bootstrap likelihood-ratio ($-2 \ln L$ difference) test, and the BVR: the AIC3 is lowest, the likelihood-ratio test shows it is significantly better than the 3-class model and non-significantly worse than the 5-class model, and the largest BVR drops quite a bit when going from 3 to 4 classes, but not anymore afterward. The AIC indicates that at least 6 classes are needed, but simulation studies have shown that it tends to overestimate the number of classes.

As also happens in this example application, different criteria typically point at different “best” models, meaning that either preference for parsimony and/or content knowledge should determine the final decision, in this example, on whether to retain the 3- or 4-class model. The last column of **Table 4** reports the entropy-based R^2 value indicating how well one can predict the individuals’ class memberships based on their observed responses. As in our example, this measure typically decreases with the number of classes. It should be noted that it should not be used for model selection, but only as a measure indicating how well the selected model performs in terms of classification (similar to a reliability coefficient of a scale).

Software

One of the first LC analysis programs, MLLSA, made available by Clifford Clogg in 1977, was limited to a relatively small number of nominal variables. Today’s programs can handle many more variables, as well as other scale types. For example, the LEM program (Vermunt, 1997) provides a command language that can be used to specify a large variety of models for categorical data, including LC models. Mplus is a command language-based structural equation modeling package that implements many types of LC and mixture models. In addition, routines and packages for the estimation of specific types of LC models are available for SAS, R, and Stata (see, for example, Lanza et al., 2007; Linzer and Lewis, 2011; Skrondal and Rabe-Hesketh, 2004). Haughton et al. (2009) reviewed the Latent GOLD program and the R packages poLCA and MCLUST.

Latent GOLD (Vermunt and Magidson, 2016, 2021) is a stand-alone program that was especially developed for LC analysis, and which contains both an SPSS-like point and click user interface and a syntax language. It implements all important types of LC models, such as models for response variables of different scale types, restricted LC models, models with predictors, models with local dependencies, models with multiple discrete latent variables, path models with discrete latent variables, latent Markov/transition models, mixture regression and mixture growth models, mixture factor analysis and IRT, multilevel LC models, three-step LC modeling, and LC tree models, as well as features for dealing with partially missing data, performing bootstrapping, generating multiple imputed data sets, performing simulation studies, and providing correct inference with complex sampling designs.

Education researchers are often interested in findings heterogeneous patterns in longitudinal data. Growth mixture modeling (GMM) is a statistical approach that models such heterogeneity by classifying individuals with similar longitudinal patterns into groups (termed latent classes) (Muthén and Shedden, 1999; Wickrama et al., 2016). The purpose of this article is to illustrate the use of GMM within the field of education research via an examination of students' mental health over time (i.e., repeated measures of depressive symptoms). To accomplish this objective, we provide an overview of GMM, highlight the strengths of this analytical approach, and review specific GMM analytical strategies, in addition to providing specific step-by-step examples following the three steps of GMM model specification recommended by Wickrama et al. (2016): (a) model estimation, (b) addressing estimation problems, and (c) model selection and interpretation. We begin by briefly reviewing latent growth modeling (LGM), which serves as the measurement (or baseline) model for GMM.

A latent growth model

A latent growth model (LGM) is a type of longitudinal structural equation model that allows researchers to evaluate an individual's change (trajectory) over time (Meredith and Tisak, 1990; Wickrama et al., 2016). A LGM can be considered as two different processes capturing intra- and inter-individual change. First, a latent initial level and a latent slope (i.e., the growth factors) are estimated based on each individual's trajectory (known as intra-individual changes; Wickrama et al., 2016). Second, growth factors estimate the *average* trajectory and *variation* across individuals' trajectories (known as inter-individual variation). Therefore, a LGM allows researchers to examine individual trajectories over time and individual differences in these trajectories simultaneously. The LGM begins with the premise that a set of repeated measures are functionally related to the passage of time. For example, with a set of repeated measure of students' depressive symptom scores, a LGM can be specified as follows.

$$\text{Depressive Symptoms}_{it} = \pi_{0i} + \pi_{1i} \times t + \varepsilon_{it}, \quad \varepsilon_{it} \sim \text{NID}(0, \sigma_t^2) \quad (1)$$

where there are $i = 1, 2, \dots, n$ respondents, $t = 0, 1, 2, \dots, t-1$ timepoints (assuming linear changes), and ε_{it} = the error term for the i th individual at time t (assuming that error, ε , is normally and independently distributed with a mean of 0 and a variance of σ^2). Because each person has their own intercept (π_0) and slope (π_1), we have as many intercepts and slopes as we have study participants (n). The univariate (i.e., unconditional) version of this model can be written as:

$$\pi_{0i} = \mu_{00} + \zeta_{0i}, \quad \text{where } \zeta_{0i} \sim \text{NID}(0, \psi_{00}) \quad (2)$$

$$\pi_{1i} = \mu_{11} + \zeta_{1i}, \quad \text{where } \zeta_{1i} \sim \text{NID}(0, \psi_{11}) \quad (3)$$

$$\psi = \begin{bmatrix} \psi_{00} & \\ \psi_{10} & \psi_{11} \end{bmatrix} \quad (4)$$

where there are $i = 1, 2, \dots, n$ respondents in the study, μ_{00} and μ_{11} represent the average intercept and slope, and ζ_{0i} and ζ_{1i} indicate the errors of the estimated intercepts and slopes around their means (assuming that the errors are normally and independently

Fig. 1 A specification of linear latent growth model with five repeated measures of depressive symptoms. Note. Var. = variance. Cov. = covariance.

distributed). ψ_{00} and ψ_{11} represent the error variance of the intercept and slope, respectively. The parameter μ_{11} describes the average overall rate of change in individuals' depressive symptoms, or the mean trajectory of depressive symptoms across the sample, while the population variance for the change parameter (ψ_{11}) reflects individual differences in the rate of change. ψ_{10} denotes the covariance between π_{0i} and π_{1i} .

In a LGM, these two processes are represented through the specification of latent (i.e., unobserved) variables referred to as (a) *initial level* and (b) *slope* (rate of change). Using five repeated measures of students' depressive symptoms, **Fig. 1** shows a LGM model specification. The *initial level* variable reflects the level of depressive symptoms at the first measurement occasion (i.e., depressive symptom 1). The initial level estimate is the expected initial value (i.e., students' scores of latent initial level factor) of depressive symptoms for each individual in the sample. Because the initial level factor is constant over time, the factor loadings are fixed to 1 for the repeated measures. The latent slope factor estimates the constant (absolute) change in depressive symptoms over time (e.g., the rate of change for the repeated variable, depressive symptoms, from timepoint 1 to 5). This constant change of an attribute is sometimes termed a maturation effect to represent the effect of aging or development over time. The *slope* variable (i.e., students' scores for the latent slope factor) reflects the rate of change in depressive symptoms across the five timepoints. Time (e.g., age, day, or wave of measurement) is built into the factor loading matrix to form the hypothesized trajectory. The most common form, or shape, for a trajectory models a linear trend over time. For instance, with data from five time points equally spaced one year apart, the factor loadings for the slope are 0, 1, 2, 3, and 4 for timepoints 1 through 5, respectively (see a latent slope factor in **Fig. 1**). Note that non-linear trajectories, such as quadratic trajectories, can also be specified by adjusting the time loadings (e.g., $t = 0, 1, 4, 9$, and 16). See Wickrama et al. (2016) for more details about non-linear trajectory specification for a LGM. Residuals (ϵ) for the repeated measures reflect the unexplained variance (σ^2) of repeated outcomes (e.g., depressive symptoms) at each timepoint after accounting for effects of trajectories.

Means (μ_{00} and μ_{10} ; known as fixed effects) and variances (ψ_{00} and ψ_{11} ; known as random effects reflecting the degree of inter-individual variability, or differences, in trajectories) are estimated for the latent growth factors (initial levels and slopes). The covariance between initial level and slope, ψ_{10} , representing the (rank-order) association between the initial level and the growth (i.e., slope) is also estimated for the sample. A negative covariance between the initial level and slope factors would suggest that students with greater values at timepoint 1 (relative to other students in the study) tended to have a steeper decline (or less positive growth) in depressive symptoms over time.

To evaluate model fit, the chi-square (χ^2) statistic is typically examined. A χ^2 with a significant p -value indicates that the hypothesized model is a poor fit to the data. However, the χ^2 statistic is sensitive to sample size and is commonly significant when the sample size is large (Little, 2013; Wickrama et al., 2016). Alternatively, other fit indices can be examined, such as the Comparative Fit Index (CFI, ≥ 0.90 acceptable fit; Little, 2013) and Root Mean Square Error of Approximation (RMSEA, ≤ 0.08 acceptable fit; Little, 2013).

Potential heterogeneity in individual trajectories

In some instances, latent growth modeling is not well-suited for studying change because of the inherent heterogeneity in the trajectories of the specific attributes examined. For example, students' health attributes are typically not uniformly distributed throughout the population. Instead, qualitatively different trajectories may exist within the population. As a result, individual trajectories of various health attributes may be heterogeneous, or clustered. For instance, classes, or groups of students, may exist with variations in depressive symptoms, including one group with consistently low and stable symptoms and another group with moderate and increasing symptoms. There may also be instances where study attributes do not have a common growth trend (e.g., linear or non-linear trajectory).

In the longitudinal context, heterogeneity, or clustering, of individual trajectories may be characterized into distinct sub-populations for two reasons. First, the heterogeneity, or clustering, of individual trajectories can be based merely on the rates of change (slopes) across individuals. That is, even though all individuals share a common growth trend/function (e.g., all respondents share a linear growth pattern), there could be three [or more] clusters based on the rate of change. For example, sub-populations with varying rates of change could include linear and increasing, linear and decreasing, and linear but constant. The heterogeneous rate of change across individuals produces different patterns resulting in unobserved variation. In considering student mental health trajectories, sub-populations may include those who are chronically mentally ill, those with deteriorating mental health, and those who are generally healthy or have improving mental health. Although all of these sub-populations share a common linear growth function, they have meaningfully different average rates of change (and/or different initial levels). These differences result in different growth patterns.

For example, research suggests several distinct sub-populations exist for youths' depressive symptoms trajectories (e.g., [Lee et al., 2017](#)). These trajectories represent normative (chronically low) levels of depressive symptoms, escalating depressive symptoms, and recovering (decreasing) depressive symptoms. Panel A of [Fig. 2](#) illustrates the observed individual trajectories of depressive symptoms for all individuals in the present sample of 436 students between the ages of 13 and 16. This figure does not show an overall trend in depressive symptoms over time. Panel B of [Fig. 2](#) shows randomly selected trajectories of depressive symptoms belonging

Panel A. Observed Individual Trajectories (Growth Model Approach)

Panel B. Unobserved Heterogeneity in Depressive Symptom Trajectories for the Consistently Low, Recovering, and Escalating Classes.

Fig. 2 Individual depressive symptom trajectories for members of each trajectory class.

to the three identified trajectory classes. The individuals in these classes exhibited different patterns of change. These distinct patterns of change suggest the assumption of a single population and/or a single growth function is an oversimplification. Instead, the results support the existence of heterogeneous growth with different growth patterns across unique sub-populations. Although it is not possible to extract distinct patterns of trajectories in a LGM, one way to examine this further is through the use of growth mixture modeling, which we discuss in detail in the next section.

Growth mixture modeling

A growth mixture model (GMM) is a specific type of LGM. A major analytic goal of growth mixture modeling is to examine distinct patterns (or Heterogeneity) in growth parameters (i.e., means and variances of initial levels and slope) over time (Wickrama et al., 2016). This approach assumes that the population consists of distinct sub-groups of trajectories (that is, a “mixture” of distributions), thereby accommodating for the existence of heterogeneous trajectories or latent classes of trajectories. Thus, using a GMM is more appropriate than a simple LGM for the investigation of individual trajectories when there is heterogeneity in the trajectories of interest (Muthén and Muthén, 2000).

As shown in Fig. 3, a GMM allows for heterogeneity by extending a LGM to incorporate latent categorical variables (C) in addition to continuous latent growth factors (initial level and slope) within the same modeling framework. (Note that C represents latent classes of individual trajectories). Thus, a GMM fully captures inter-individual variation (i.e., within-class variation) in individual growth trajectories like a LGM, while also taking into account between-class variation (i.e., unobserved heterogeneity). In

Fig. 3 A linear growth mixture model (GMM). Note. Var. = Variance. Cov. = Covariance. Class $k = 1, 2, 3, \dots K$.

other words, a GMM assumes that the mixture of within-class normal distributions of latent growth factors (initial level and slope) corresponds to several classes that have between-class variation (Bauer and Curran, 2003; Feldman et al., 2009).

Specifying a growth mixture model

As previously discussed, a GMM includes a latent categorical variable, C , that specifies each individual's membership in a certain class. In a GMM, individuals are assigned to one of the categories (or latent classes) with distinct growth patterns (intercept and slopes) according to the individual's growth pattern. Unlike other strategies, such as multi-group growth modeling which requires *a priori* knowledge of each individual's group membership (e.g., a gender which is a categorical grouping variable with two categories), the group assignment in a GMM is latent and "determined" as part of the estimation routine. That is, a GMM identifies *unobserved (latent) subpopulations* and describes the growth patterns of each unobserved sub-population along with examining differences in growth patterns for these unobserved (latent) sub-populations.

Fig. 3 shows the growth parameters in class k ($= 1, 2, \dots, K$). For example, μ_{k00} and μ_{k10} represent the average initial levels and slope in latent trajectory class k . ψ_{k00} and ψ_{k11} are the error variances of the estimated intercept and slope factors in class k , and ψ_{k10} is the covariance between the intercept and slope factors within the latent trajectory class k . The k subscript indicates that most parameters are allowed to vary between the estimated latent trajectory classes. Thus, each latent trajectory class could be defined by its own LGM based on class-specific parameters consisting of (1) means (i.e., μ_{k00} and μ_{k10}) of growth factors, (2) variance and covariance structures (ψ_{k00} , ψ_{k11} , and ψ_{k10}) of the growth factors, and (3) residual variances of manifest indicators (i.e., σ_{kt}^2).

Building a growth mixture model using Mplus¹

A GMM with unbiased model parameters can be estimated in Mplus in four steps.

- Step One Specify a latent growth model (LGM)
- Step Two Specify a growth mixture model (GMM)
- Step Three Address estimation problems
- Step Four Select the optimal unconditional model

For the illustrative purpose of these four steps, we use data from adolescents from rural families in the Midwest who participated in a panel study; Family Transition Project, (FTP; Principal Investigator [PI]: R. D. Conger). Additional information regarding the study procedures is available from Wickrama et al. (2016). Nine items from the SCL-90-R (Derogatis and Melisaratos, 1983) were used to assess adolescents' self-reported depressive symptoms in 1991, 1992, 1994, 1995, and 1997 on a 5-point Likert scale from 1 = *not at all* to 5 = *extremely*. For each timepoint, a mean score was computed with higher values indicating more depressive symptoms. The measure's internal consistency (α) was greater than .90 across timepoints.

Specify a latent growth model (step one)

Before fitting a GMM to the data, a LGM can be estimated to determine if the LGM assumptions of uniform variation with a common growth function are valid. That is, fitting a LGM to the data allows the researcher to examine the overall fit of the data to a trajectory with a single shape or form before considering trajectory heterogeneity. We recommend examining two important model results from this stage: model fit indices and variances of the growth factors. Poor fit indices and statistically significant variances of growth factors suggest the existence of heterogeneous trajectories, or sub-populations, with distinct trajectories.

Illustrative example: Mplus syntax for a latent growth model

Mplus syntax (version 8.4) for the latent growth model is as follow:

```
VARIABLE: NAMES ARE DEP1-DEP5; USEVAR = DEP1-DEP5; MISSING = all (-999);
MODEL:
  I S | DEP1@0 DEP 2@1 DEP 3@3 DEP 4@4 DEP 5@6;
OUTPUT: SAMPSTAT;
PLOT: SERIES = DEP1-DEP5(S); TYPE = PLOT3;
```

Note that DEP1–DEP5 indicate depressive symptoms at timepoints 1, 2, 3, 4, and 5. This syntax specifies factor loadings for a linear change proportionate to the unequal time intervals of the current example data ($t = 0, 1, 3, 4$, and 6). For the purpose of illustrating the model, we specified a linear growth function model; however, as mentioned previously, a non-linear growth function, such as a quadratic function, could also be estimated. Regarding the model results, the model fit indices suggested that the LGM fit the data poorly ($\chi^2(df) = 70.741(10)$, $p < 0.001$, RMSEA (90%) = 0.117 (0.093, 0.145). CFI/TLI = 0.892/0.892, SRMR = 0.067). Furthermore, the variances for the growth factors were statistically significant (0.165, $p < 0.001$ and 0.004, $p < 0.001$, for the intercept and slope factors, respectively), indicating significant variation in the growth function between individuals. Together the poor model fit and the significant variances of growth factors provide some evidence of potential heterogeneity in longitudinal changes of depressive symptoms.

¹While we focus on utilizing this approach in Mplus, the analytical approach can be implemented with other software packages (e.g., R, SAS, and STATA).

Estimating a growth mixture model (step two)

Building on the LGM results that supported possible heterogeneity in the trajectories of depressive symptoms, a GMM can be estimated as a next step to investigate potential classes of adolescents with distinct symptom trajectories.

Illustrative example: *Mplus* syntax for a growth mixture model

In *Mplus*, a GMM model can be specified using the syntax shown in Figs. 4 and 5:

The bold portions of the syntax are the parts that add the GMM to the existing univariate LGM.

The TYPE = MIXTURE option specifies the mixture model algorithm. By specifying CLASSES = C(2), a two-class model is examined. If the model converges successfully and the results are interpretable, the number of classes can be increased by specifying CLASSES = C(3) followed by CLASSES = C(4), CLASSES = C(5), and so on until the optimal class model is selected. The STARTS and STITERATIONS syntax commands are not required for estimating a GMM because *Mplus* automatically sets these parameters at default values. Unless other values are specified, *Mplus* assumes 20 random sets of starting values and 4 optimizations in the final stage. However, adjusting these values may aid in obtaining successful convergence. These convergence issues are described in detail in Step 3 (Addressing estimation problems).

In the OUTPUT command, TECH7 can be specified to request sample statistics for each class. TECH8 provides the optimization history (i.e., iteration process), which is used in conjunction with STARTS and STITERATIONS. Specifying TECH11 requests the Lo-Mendell-Rubin likelihood ratio test (LMR-LRT) of model fit (Lo et al., 2001). If TECH13 is specified, univariate, bivariate, and multivariate skewness and kurtosis values are provided in the output (i.e., Mardia's measure of multivariate normality test; Muthén, 2003). TECH14 provides the bootstrapped likelihood ratio test (BLRT). We return to these tests when describing how to select the optimal class model (Step 4). Finally, the PLOT command can be used to request graphical displays of the model results. The observed and estimated means and trajectories for each class can be viewed in the graphs provided in the *Mplus* output. Using the dropdown menus in *Mplus* allows the user to view the graphs specified by the PLOT syntax (Plot → View Plots → Estimated Means and Observed Individual Values).

Mplus automatically constraints all variances and covariances of the growth factors to be equal across classes by default (i.e., variance-covariance equality). This variance-covariance equality of growth parameters can lead to problems. Simulation studies have shown that similar restrictions (i.e., equal variance-covariances) could result in the over-extraction of latent classes and biased parameter estimates (Bauer and Curran, 2004; Enders and Tofghi, 2008; Magidson and Vermunt, 2004). Thus, it may be necessary

Title: Growth Mixture Model (GMM)

DATA: File is EXAM.dat;

VARIABLE: names are DEP1-DEP5;

usevar = DEP1-DEP5;

CLASSES=C(2);

missing = all (-999);

ANALYSIS: **TYPE=MIXTURE;**

STARTS = 500 10;

STITERATIONS = 10;

LRTBOOTSTRAP=50;

MODEL: **%OVERALL%**

1 S | DEP1@0 DEP 2@1 DEP 3@3 DEP 4@4 DEP 5@6;

The **CLASSES** option defines "C" and specifies the number of classes in the mixture model.

TYPE=MIXTURE is required for mixture models.

STARTS is used to specify the number of randomly selected starting values.

STITERATIONS is used to specify the maximum number of iterations allowed in the initial stage.

LRTBOOTSTRAP is used in conjunction with the TECH14 option to specify the number of bootstrap draws to be completed when estimating the *p*-value of the true 2 time log-likelihood distribution.

%OVERALL% specifies an overall mixture model.

OUTPUT: SAMPSTAT STANDARDIZED MOD (5.00) **TECH7 TECH8 TECH11 TECH13 TECH14;**

PLOT: SERIES = DEP1-DEP5(S); TYPE=PLOT3;

TECH7 requests the sample statistics for each class.

TECH8 requests the optimization history (i.e., iteration process).

TECH11 requests the Lo-Mendell-Rubin likelihood ratio test that compares *k*-1 class model to the *k*-class model.

TECH13 requests the multivariate skewness and kurtosis test.

TECH14 requests a parametric bootstrapped likelihood ratio test that compares the *k*-1 class model to *k*-class model.

Fig. 4 *Mplus* syntax for a growth mixture model (GMM). Note. I = initial level. S = slope. Dep = depressive symptoms.

to free some (or all) of the within-class variances. Adding the syntax below to the model command of the GMM syntax frees the variances and covariances:

```
MODEL: %OVERALL%
I S | DEP1@0 DEP2@1 DEP3@3 DEP4@4 DEP5@6;
%C#1%
[I-S](M1-M2);
I-S (V1-V2);
I WITH S (COV1);
%C#2%
[I-S](M3-M4);
I-S (V3-V4);
I WITH S (COV2);
MODEL TEST:
M1=M3;
```

The bold commands allow the unique variances and covariances of the intercepts and slopes to be freely estimated for each class. Also, these syntax options make it possible to test hypotheses about all growth parameters (i.e., mean and variance-covariance parameter equality across classes; invariance test of growth parameters) using a Wald chi-square test (i.e., likelihood ratio test, LRT; [Morin et al., 2011](#)). This test is often utilized when selecting the optimal modeling approach (e.g., a model with equal variance-covariances in all classes or a model with freely estimated variances-covariances). We assigned names in parentheses to all growth parameters (e.g., M1, M2, and V1, etc.) to enable use of the MODEL TEST command to test a series of parameter constraints. The lines following the MODEL TEST command provide the specific constraints to be tested. For descriptive purposes, in the current example, we specify the null hypothesis that $M1 = M3$. This corresponds to the null hypothesis that the mean trajectories of depressive symptoms are equal across two classes.

Researchers can also fix the variance and covariance of specific growth parameters to zero (a partially constrained GMM) by adding the appropriate syntax under each class specification. For example, to fix the growth parameters of Class 2 to 0, the following syntax is added:

```
%C#2%
I-S@0; I WITH S@0
```

By assigning labels to the variance-covariance parameters, these constrained variance-covariances can be tested using a Wald chi-square test (i.e., specifying MODEL TEST in the model command).

Regardless of the GMM specification, this approach is exploratory and driven by the data utilized. As such, the results may not align with theoretical expectations or hypotheses. Consequentially, when employing this type of exploratory approach to model specification, results should be treated circumspectly. The decisions about class identification should be based on theory, interpretability, prior research, and practical considerations (e.g., model convergence and computational speed time).

Addressing estimation problems (step three)

Certain estimation difficulties are relatively common with mixture models and can lead to a non-optimal or non-estimated class solution. Previous literature has reported several reasons for these estimation problems. First, the probability distribution of the indicators used for constructing the classes may not be normal ([Bauer and Curran, 2003](#)). Second, there can be convergence problems related to a “local solution” ([Hipp and Bauer, 2006](#)). Third, the model may not converge due to inappropriateness of the data and/or non-identification of the model ([Collins and Lanza, 2010](#); [Wurpts and Geiser, 2014](#)). We explain each of these common problems in the sections that follow.

Estimation problems related to the non-normal probability distribution

When estimating a GMM, the number of latent classes identified may be incorrect due to the nature of the distribution of the observed data (e.g., multivariate skewness or non-normality; [Bauer and Curran, 2003](#)). In latent growth modeling, it is assumed that the repeated measures are normally distributed (i.e., multivariate normality). This implies that the random coefficients (intercept and slope) and time-specific residuals are also normally distributed ([Verbeke and Molenberghs, 2000](#)). However, based on the statistical theory of finite normal mixture models, in a GMM, the normality assumption is relaxed to accommodate the mixture of several normal distributions corresponding to the different classes. These classes may have different mean structures and variance-covariance structures. That is, in a GMM, normality is only assumed within the classes (i.e., within-class normality), and heterogeneity is a characteristic of the residuals. However, if the repeated measures data are not normally distributed, finite normal mixture models, such as a GMM, can erroneously estimate latent class trajectories in the absence of population heterogeneity. Particularly, there is the possibility of over-extracting latent trajectory classes in a homogeneous, non-normal distribution ([Bauer and Curran, 2003](#)). This over-extraction makes generalizing the finding of heterogeneous classes to the larger population doubtful.

To increase the accuracy of latent class trajectory identification, we recommend assessing the normality of the data before selecting the optimal class model. To assess multivariate normality, [Hayduk \(1987\)](#) suggested that each univariate distribution should have a normal distribution. Thus, the univariate skewness and kurtosis statistics should be investigated. Values less than ± 2.00 are generally accepted for normal distributions ([George and Mallery, 2010](#)).

Estimation problems related to local maxima

In the estimation process, the highest log-likelihood value should be replicated when the optimal class solution is achieved. Thus, “local maxima” problems can result in an incorrect class solution. With maximum likelihood estimation (MLE), the model solution is provided when the likelihood ratio reaches a replicable maximum value through an iterative optimization process. This iterative optimization process consists of two stages: (1) the initial stage, which is generated from the given starting values, and (2) the final optimization stage (Myung, 2003). The iterative optimization process could stop prematurely and return a sub-optimal set of parameter values depending on the choice of the initial starting values (chosen either at random or by the researcher). When the highest log-likelihood value is not replicated, a “local maxima” or “local solution” was obtained.

It is good practice to run the model with multiple random sets of starting values to guarantee that the global solution is obtained and avoid “local maxima” (Hipp and Bauer, 2006). The global solution has the highest log-likelihood value (i.e., the best solution). Jung and Wickrama (2008) suggested that between 100 and 500 random sets of starting values are necessary to locate the global solution (i.e., the highest log-likelihood value as opposed to a local solution) (see the “STARTS = 500 10” statement in Fig. 4).

Estimation problems due to model non-identification and inappropriate data

When the model is not identified (i.e., an under-identified model), the model does not converge and no standard errors (and related p -values) or other meaningful estimates are estimated. Non-identification is often due to model complexity; that is, models often fail to converge when too many parameters are estimated simultaneously. In these instances, an error message is printed in the output, and the user needs to re-specify the model, most commonly, by constraining some parameters (Muthén and Muthén, 2012). Non-convergence may also occur when data are used inappropriately (Muthén and Muthén, 2012). For example, some researchers may be interested in examining trajectories of major depressive disorder (0 = No or 1 = Disorder). In these situations, it would be important to model the data as having a logistic or probit distribution rather than as having a continuous normal distribution (Lee et al., 2018).

Selecting the optimal class model (step four)

After successful convergence and support for a global solution, the final step is to select the optimal class model. With other model types, chi-square values are the primary criteria for selecting the optimal model. However, in a mixture model, the chi-square values are not very useful for determining the optimal model because the likelihood ratios between the k -class and $k-1$ class model do not follow a chi-square distribution (Feldman et al., 2009; Muthén, 2003). Thus, it is necessary to investigate multiple model fit indices to select the optimal model. Various indices have been suggested; they fall into three categories (Feldman et al., 2009; Jung and Wickrama, 2008; Nylund et al., 2007):

- (1) Information criteria (IC) statistics, such as the Bayesian information criterion (BIC) and the sample size-adjusted BIC (SSABIC),
- (2) Entropy values, and
- (3) likelihood ratio tests (LRT), such as the Lo-Mendell-Rubin likelihood ratio-test (LMR-LRT) and the bootstrapped LRT (BLRT) (Tein et al., 2013).

Information criteria (IC) statistics

IC statistics are generally computed using the deviance statistics (-2 log-likelihood values), the number of model parameters (p), and sample size (n). IC statistics incorporate a parameterization penalty for models with a large number of parameters (as an indicator of high model complexity) and/or small sample size. In general, lower values of the Bayesian information criterion (BIC) and sample size adjusted BIC (SSABIC) values indicate a better model fit (Feldman et al., 2009).

Entropy and average posterior probabilities

Entropy is a standardized index (i.e., range = 0 to 1) of model-based classification accuracy. Higher values indicate improved enumeration accuracy, which signals clear class separation (Feldman et al., 2009; Nagin, 2005). Entropy is estimated based on the average posterior probabilities (Muthén, 2004). Thus, an entropy value of zero indicates that the posterior probability of class membership does not vary across classes (no class separation). In contrast, an entropy value of one indicates that, for any given individual, there is perfect posterior probability (value of 1) for membership in one class with no posterior probability (value of 0) for membership in other classes, signaling perfect class separation). According to Clark and Muthén (2009), entropy values of 0.40, 0.60, and 0.80 represent low, medium, and high class separation. The entropy statistic is provided in the *Mplus* output along with the average posterior probability for each class. Like the entropy statistic, in general, high probabilities indicate that the classes are distinct from each other. For example, a probability of 0.91 suggests that 91% of subjects in the assigned class fit that category, while 9% of the subjects in that given class do not accurately fit that category (Fanti and Henrich, 2010).

Likelihood ratio test (LRT): LMR-LRT and bootstrapped LRT (BLRT)

Two LRTs, the Lo-Mendell-Rubin likelihood ratio test (LMR-LRT; Lo et al., 2001) and the bootstrapped likelihood ratio test (BLRT; McLachlan and Peel, 2000) are often used for model comparison when determining the optimal number of classes. The LMR-LRT compares two adjacent class models ($k-1$ and k -class model) (Lo et al., 2001). Like the SSABIC, an adjusted LMR-LRT (Adj. LMR-LRT) statistic accounting for sample size is provided in *Mplus* (Muthén, 2004).

McLachlan and Peel (2000) also developed another LRT known as the bootstrapped LRT (BLRT). Using this approach, the likelihood ratio test (LRT) between the $k-1$ and k -class models is conducted through a bootstrapped procedure (Asparouhov and Muthén, 2012). The bootstrap draw can be manually specified using the LRTBOOTSTRAP option in the ANALYSIS command (The default number varies from 2 to 100). For example, the following syntax specifies 50 bootstrap draws (see the corresponding syntax in Fig. 4).

LRTBOOTSTRAP = 50; 100 bootstrap draws has been suggested by past research for the estimation of a more precise p -value (McLachlan and Peel, 2000). In both tests (LMR-LRT and BLRT), the difference in log-likelihood values between the $k-1$ and k -class models is calculated and inference statistics are provided (p -values). Significant p -values indicate that the k -class model (i.e., the current model) provides a better fit than the $k-1$ class model (i.e., a model with one less class).

In the *Mplus* output, both LRTs (i.e., LMR-LRT and BLRT) provide the difference of log-likelihood values between the $k-1$ class model and the k -class model. A low p -value for both statistics indicates that the current k -class model is a significantly better fit to the data than a model with one less class. In most cases, the BLRT outperforms the LMR-LRT and other IC statistics (Nylund et al., 2007; Tein et al., 2013). However, the BLRT is more sensitive to non-normal distributions and model complexity, which can lead to convergence problems (Nylund et al., 2007). If a local solution is detected in either the $k-1$ class or the k -class model (or both models), the difference between the log-likelihood values will be biased. In turn, this leads to biased inference statistics (p -values). As such, the more robust LMR-LRT is generally preferred (Nylund et al., 2007). In the "Model fit information" section of the *Mplus* output, IC statistics and the entropy statistic are provided. However, the LMR-LRT and BLRT are only shown when TECH11 (for LMR-LRT) and TECH14 (for BLRT) are specified in the syntax (see the corresponding syntax in Fig. 4).

Other considerations

In addition to these three classes of model fit indices used for selecting the optimal number of classes, there are other factors that should be considered (Feldman et al., 2009). Enumerating the number of latent classes in a GMM is not a simple identification procedure based solely on model fit indices. For example, researchers can consider conventional model comparison approaches. If similar information (e.g., fit indices) is provided for both $k-1$ and k -class models, the more parsimonious model (i.e., the model with fewer classes) is preferred (Feldman et al., 2009). An additional consideration is the sample size of the smallest class. If the smallest class contains less than 5% of the sample and/or the sample size for the smallest class is less than 25, it is recommended that the model only be retained as the optimal model if the researcher can accurately defend what is gained from this small class given the possibility of low power and a lack of statistical precision (Berlin et al., 2014; Lubke and Neale, 2006). Finally, the interpretability of each class trajectory is essential. Plots often provide useful information when selecting the optimal class model. When viewing the plots, each class trajectory should be clearly distinct and separate from other classes. The classes should also be interpretable and consistent with theory.

Illustrative example: identifying the optimal model

Using our example model (i.e., repeated measures of depressive symptoms from Time 1 to Time 5; DEP1 to DEP5), we illustrate how to select the optimal class model. We first examined the model fit indices for the two-class model and compared those indices with indices from the model with three classes. This process continued incrementally by fitting models with a larger number of classes until model fit ceased to improve. Furthermore, to avoid the possibility of a local maxima, 500 random sets at the initial stage and 10 final optimizations were specified for all models (STARTS = 500 10). Note that, for model simplicity, only a linear trajectory was assessed. Table 1 provides the model fit indices for these incremental GMMs with two to five classes.

As shown in Table 1, no convergences problems (i.e., local maxima) were detected across the class models. The 5-class model had the lowest BIC and SSABIC values, supporting the 5-class model as the preferred model. However, the 4- and 5-class models had classes with small group sizes. The smallest class sizes were 5 (1.1%) and 6 (1.4%) for the 4- and 5-class models, respectively. Also, the output suggests that estimation of the BLRT in the 5-class model is biased. Taking these results into consideration, the 3-class model was selected as the optimal model. The model fit indices suggest that the 3-class model was a better fit to the data than the 2-class model (lower BIC and SSABIC values, higher entropy value [with average posterior probabilities ranging from 0.898 to 0.990], and a statistically significant p -value for the BLRT). While the p -value for the LMR-LRT was not statistically significant (indicating that the 3-class model does not improve the model fit), Nylund et al. (2007) reported that the BLRT outperforms the LMR-LRT when a local solution is not detected.

Growth parameters for each optimal model are shown in Table 2. Most growth parameters (i.e., means and variances) in this 3-class model were statistically significant. The distinct patterns of (mean) trajectories for each class suggest that longitudinal changes in students' depressive symptoms differ by classes. Also, within a class, there was significant inter-individual variation in growth factors (initial level and slope), indicating that individual trajectories varied within a class.

Consistent with these previous findings noting heterogeneity in depressive symptoms trajectories (Wickrama et al., 2008), the results in Table 2 suggest the existence of three general trajectory patterns. These three patterns include: (1) a consistently low symptom trajectory, (2) an initially low or moderate and increasing symptom trajectory, and (3) an initially high and decreasing symptom trajectory. Combining the information gathered from the model fit statistics, plots, and relevant theory, we selected the three-class GMM model as the optimal class model.

Table 1 Fit statistics for incremental GMMs (total N = 436).

Fit statistics	2 classes	3 classes	4 classes	5 classes
LL (no. of parameters)	−963.282 (13)	−918.234 (16)	−887.040 (19)	−853.867 (22)
BIC	2005.564	1933.711	1889.555	1841.443
SSABIC	1964.318	1882.935	1829.258	1771.627
Entropy	0.974	0.953	0.957	0.939
Adj. LMR-LRT (<i>p</i>)	<i>216.795 (0.00)</i>	85.411 (0.20)	58.615 (0.12)	62.895 (0.16)
BLRT (<i>p</i>)	<i>228.685 (0.00)</i>	<i>90.096 (0.00)</i>	61.830 (0.00)	66.344 (0.00) ^a
Group size (%)				
C1	27 (6.2%)	20 (4.6%)	5 (1.1%)	6 (1.4%)
C2	409 (93.8%)	38 (8.7%)	21 (4.8%)	11 (2.5%)
C3		378 (86.7%)	33 (7.6%)	32 (7.4%)
C4			377 (86.5%)	34 (7.7%)
C5				353(81.0%)

Note. LL = Log-Likelihood value. No. of Parameters = Number of estimated (freed) parameters. BIC = Bayesian Information Criteria. SSABIC = Sample Size Adjusted BIC. LMR-LRT = Lo-Mendell-Rubin Likelihood Ratio Test. Adj. LMR-LRT = Adjusted LMR. BLRT = Bootstrap Likelihood Ratio Test. *p* = *p*-value. Bold and italic values indicate the best values for the model fit statistics in the set of models listed in the corresponding row.

^aNo replicated log-likelihood value (H0 log-likelihood value) of the *k*-1 class model.

Table 2 Growth parameters across the three classes in the optimal GMM.

	Intercept		Linear slope		Factor covariance
	Mean	Variance	Mean	Variance	
C1 (high and decreasing)	2.651***	0.050***	−0.187***	0.001*	−0.003*
C2 (low and increasing)	1.432***	0.050***	0.181***	0.001*	−0.003*
C3 (consistently decreasing)	1.374***	0.050***	−0.023***	0.001*	−0.003*

Note. C = Class. Unstandardized coefficients are shown. **p* < 0.05. ***p* < 0.01. ****p* < 0.001.

Conclusion

This chapter provides an overview of growth mixture modeling (GMM), characterized as an extension of latent growth modeling (LGM) and demonstrates the strengths of this approach via a practical illustration. Whereas LGM applications typically assume that the sample is comprised of a single population with a single set of growth parameters (e.g., means, variances, covariances). With GMM, this assumption is relaxed to allow for unobserved subpopulations drawn from latent classes with different growth parameters for each subpopulation. Thus, using GMM, researchers can identify and better understand various groups and patterns of change that may exist within a dataset. In illustrating the application of GMM with an example exploring adolescents' depressive symptoms, we found three distinct patterns of longitudinal change in their depressive symptoms. We hope our illustrations serve as a guide for other researchers and prompt increased interest in the use of GMM as we believe this approach is a useful tool for examining research questions centered on the students' health developments.

Introduction

The goal of a statistical analysis is to estimate properties of a population from sampled data. Examples are the distribution of a test score for arithmetic ability and the difference between boys and girls with respect to the mean test score for arithmetic ability. The researcher may test hypotheses, for example, whether the distribution is normal and the difference is significant. Nonparametric methods are appropriate when certain assumptions about distributions that common parametric methods make are questionable. For example, when the sample size is small (say, less than 20) and the population distribution is skewed, the sample means do not follow a parametric Student's *t*-distribution. Consequently, the one-sample *t*-test results in a probability of exceedance (*p*-value) that is biased and therefore cannot be trusted, and valid conclusions about the population based on sample data cannot be drawn (e.g., Wilcox, 2001, pp. 1–2). A nonparametric alternative would be the Wilcoxon signed-rank test (e.g., Hollander and Wolfe, 1999, p. 36), which only assumes that the observations come from a distribution that is symmetrical about the mean, but without assuming normality or another parametric shape.

For introductory textbooks on nonparametric statistics see, for example, Siegel and Castellan (1988), Hollander and Wolfe (1999), Sheskin (2007), Kolassa (2020), and Kloeke and McKean (2020). In this entry, we consider two particular classes of widely used nonparametric methods. One class concerns methods for testing hypotheses about population properties, but without distributional assumptions that may be unreasonable in certain circumstances. Nonparametric statistical methods derive the sampling distribution without assuming a particular, restrictive parametric shape for the population quantity of interest, and for that reason, they are often referred to as *distribution-free methods*. The signed-rank test example referred to belongs to this class of nonparametric methods.

The other class concerns regression methods that can be used to study the functional relation between variables without imposing a particular parametric function on this relationship. For example, linear regression assumes a linear relationship between two interval-level variables. Many examples are conceivable where the assumption of linearity is untenable. Examples include educational progress as a function of age (e.g., Kiefer et al., 2018) and test performance (e.g., number of correct answers) as a function of ability (Sijtsma and van der Ark, 2021). One possible solution is to use a non-linear parametric function, such as the logistic function (e.g., Fox, 2015). Alternatively, one can estimate the functional relationship directly from the data (e.g., Fan and Gijbels, 1996; Fox, 2000). Nonparametric regression methods may be particularly useful to study the functional relation between an interval-level independent variable and a binary or ordinal-level dependent variable. Furthermore, estimating the shape of the relationship from the data may lead to different and interesting results that a particular parametric function, such as the linear or the logistic function, would obscure when estimated.

Nonparametric methods have several interesting properties. First, they are suited for variables at all measurement levels, including categorical data, which are common in educational research. Categorical variables have either a nominal or an ordinal measurement level, but may also represent counts of particular events. Examples of nominal variables include the kinds of arithmetic errors made by students and the assignment of each student to one of three remedial teaching methods for arithmetic. Examples of ordinal variables include the teacher's rank ordering of students with respect to perceived need of remedial teaching and the

student's attitude to learning arithmetic. An example of a count variable is the number of students in each remedial teaching program who receive help.

Nonparametric methods are also useful for interval-level variables, such as students' motivation, when samples are small and assuming a parametric population distribution is not justified. The scores are then treated as ordinal rather than interval-level variables. The price paid is that information about the distances between scores is lost and the power of statistical tests reduced. Researchers often consider this unacceptable, and incorrectly analyze their data as if the sampled scores on a variable stem from a known distribution. Research has shown that in such cases the loss of information by using nonparametric methods is not as bad as one might suspect (e.g., [Hollander and Wolfe, 1999](#), p. 1).

Second, nonparametric methods are based on weaker assumptions than parametric methods. For example, instead of *assuming* a parametric distribution for a particular statistic such as the *t*-distribution, nonparametric methods use all possible rank-orderings of the data to derive the exact distribution for the statistics of interest. Statistical models based on weak assumptions are important because their assumptions are realistic about the level of knowledge expressed in many theories in educational science. However, although distribution-free, nonparametric methods do make assumptions about population distributions. Distribution-free only means that the sampling distribution is not parametrically restricted, such as the normal distribution or the Poisson distribution would do.

Third, nonparametric statistical models are convenient because they are easy to use, but some restraint may be in order. Nonparametric methods often involve complex combinatorial mathematics that are more difficult to grasp than the assumptions underlying parametric methods. Combinatorics is notorious for running into computations that soon become unmanageable even with today's computers as sample size increases or the numbers of variables increases, and all possible patterns of scores must be computed.

This entry has the following structure. First, we review a few well-known nonparametric statistical tests from the myriad of test procedures (e.g., [Siegel and Castellan, 1988](#); [Wasserman, 2006](#)) based on known, exact sampling distributions or simulated sampling distributions when exact sampling distributions are unknown or numerically too complex to evaluate. Second, we discuss methods for nonparametric data exploration and nonparametric regression. Third, we explain how to use computer-based methods for estimating standard errors and confidence intervals, both for univariate sample statistics (e.g., a distribution's median) and regression functions. The nonparametric principles and techniques discussed are a selection of widely used techniques, but do not cover the entire domain of nonparametric methods.

To illustrate the methods, we use small numerical examples and a real-data example from the Program for International Student Assessment (PISA; [OECD, 2019](#)). PISA is a triennial international survey addressing 15-year old's performance in reading, mathematics, and science. Each wave also includes additional questionnaires on various socio-economic and education-related attitudes, such as school well-being, school environment, and attitude toward science. We used data from the Dutch population collected in 2018 ([OECD, 2019](#)). The 2018-version of the student questionnaire included several scales related to student's attitude toward reading and the accessibility of reading materials for these students such as the number of books available in their home.

Nonparametric statistical tests

Testing hypotheses about group differences

To illustrate some of the foundations of nonparametric statistics, we first consider the situation where we compare two groups. Say, the researcher studies whether students receiving game-based instruction engage in deeper learning than students receiving traditional instruction (e.g., [Bado, 2019](#)). An experiment is done in which two groups of five students are assigned to one of these two conditions. One group is instructed using the traditional approach (e.g., classroom teaching) and the other group receives game-based instructional activities. After completing the program, the students are assessed on learning outcomes, motivation and learning experience. [Table 1](#) shows hypothetical data from such an experiment. The numbers represent number-correct scores

Table 1 Fictional data for academic performance in two groups trained with different instructional methods.

Instructional method			
Traditional		Game-based	
Score	Rank among all students	Score	Rank among all students
3	1	20	10
4	2	14	6
5	3	15	7
7	5	6	4
18	9	17	8
Rank sum:	20	Rank sum:	35

on a test of 20 items reflecting learning results. The statistical question is whether the mean difference in number-correct scores between the two instructional conditions is significant. Because the samples are small, a nonparametric approach is in order.

Adopting a nonparametric statistical test, we take the students from the two groups together and order them by their test score from smallest to largest and assign rank numbers (see ranks among all students in [Table 1](#)). If the two instructional methods have the same effect, implying that the test scores in each group come from the same underlying distribution, we expect the rank numbers are evenly distributed across the two conditions. However, if one instructional method is more effective than the other method, meaning that the students in one group perform generally better, we expect most low rank numbers in one group and most high rank numbers in the other group. Hence, if we sum the ranks in each condition separately, then a higher the rank sum in, say, the game-based condition provides evidence of a positive effect of game-based teaching. The test statistic of interest is the sum of the ranks in the game-based group, which in [Table 1](#) equals 35.

Let W_s denote the rank-sum variable and w_s the observed sample value in group s (here, $s = 1$ for the traditional group and $s = 2$ for the game-based group). To test whether the treatment had a significant effect, we need the distribution of W_2 under the null hypothesis (H_0) of “no effect”; this is the null distribution. Nonparametric methods use all possible rank-orderings in the data to derive the exact distribution of the statistic of interest. Assuming random sampling, all possible arrangements of the students are equally likely under H_0 . This means that under H_0 the observed rank numbers in the game-based condition can be treated

as a random sample without replacement of five numbers out of the rank numbers 1 through 10. In total, there are $\binom{10}{5} = 252$ possible combinations, each having a probability of $1/252$. For each combination, we compute the associated value of the rank sum W_2 . The distribution of the rank sums across these combinations is the exact null distribution ([Fig. 1](#)). The probability that W_2 exceeds observed sample value = 35 is the one-tailed p -value, which equals 0.076 and corresponds to a two-tailed p -value of 0.151. These p -values are called exact p -values because they are based on the exact sampling distribution. Adopting a significance level $\alpha = 0.05$, we conclude that the sample does *not* provide evidence that the game-based instructional method is more effective than the traditional method.

The test we described is the Wilcoxon rank-sum test, better known as Mann-Whitney’s U test ([Mann and Witney, 1947](#); [Wilcoxon, 1945](#)), with the difference that the latter defines the test statistic using a rescaled version of the rank sum. The rescaled value has a fixed lower bound of 0, which is obtained when in the common ranking the persons from one group occupy the lowest positions and the persons from the other group the highest positions. Then, the groups are maximally separated, that is, the maximum effect is found. Hence, statistic U thus has a more straightforward interpretation. For the Mann-Whitney U test, let n_1 be the sample size and R_{+1} the rank sum in group 1, and let n_2 and R_{+2} be the sample size and rank sum in group 2. Mann-Whitney U is defined as U_1 or U_2 , whichever is smaller, where

$$U_1 = n_1 n_2 + \frac{n_1(n_1 + 1)}{2} - R_{+1},$$

$$U_2 = n_1 n_2 + \frac{n_2(n_2 + 1)}{2} - R_{+2}.$$

In [Table 1](#), $U_1 = 20$ and $U_2 = 5$; hence, Mann-Whitney’s U equals 5. Notice that if group 1 contains the five lowest rank numbers (i.e., 1 through 5), we have $U_1 = 0$ and $U_2 = 25$, and thus $U = 0$.

The example shows some important features of nonparametric methods. First, nonparametric methods use combinatorics to derive exact null distributions. This works well for small samples (say, less than 20 observations), but as sample size increases, the number of combinations grows exponentially and the exact evaluation soon is impossible. Fortunately, for many nonparametric statistics the sampling distribution converges to the normal distribution as sample size increases. Then, one uses large-sample

Fig. 1 Exact sampling distribution for Wilcoxon’s rank-sum statistic in the traditional group (W_2).

approximations to test the hypotheses of interest. For example, for the Wilcoxon rank-sum statistic W_2 , the large-sample approximation is the normal distribution with mean

$$E_{H_0}(W_2) = \frac{n_2(N+1)}{2} = \frac{5(10+1)}{2} = 27.5$$

and variance

$$\sigma_{H_0}^2(W) = \frac{n_1 n_2 (N+1)}{12} = \frac{5 \cdot 5 \cdot 11}{12} = 22.92.$$

The normalized value of W_2 then equals

$$Z_{W_2} = \frac{w_2 - E_{H_0}(W_2)}{\sqrt{\sigma_{H_0}^2(W)}} = \frac{35 - 27.5}{\sqrt{22.92}} = 1.57$$

and the corresponding two-tailed p -value, which in this case equals 0.117, is obtained from tables for the normal distribution or using standard software. The normal distribution is continuous, whereas statistic W_s is discrete. Continuity corrections exist to account for the discreteness of the rank sums. In our example, the continuity corrected two-tailed p -value equals 0.144. Finally, the independent samples t -test would yield a two-tailed p -value of 0.088. If we were to test at the 10% significance level, we would reject H_0 using the independent samples t -test, but not if we would use the Mann-Whitney test. In this case, it matters which statistical test one chooses for the conclusions of the study.

Second, the example shows another feature of nonparametric statistics, which is the use of permutation tests. Permutation tests are used to evaluate hypotheses defined by rank-order information. If the number of permutations is too large to evaluate hypotheses, then one replaces the ambition to evaluate all by a large albeit limited number of random permutations and computes the Monte Carlo p -value (Davison and Hinkley, 1997, pp. 141–142). This approach circumvents either making assumptions about the distribution of the variables, as the independent samples t -test does, or relying on asymptotic large-sample approximations, but the number of simulated replications must be very large.

Third, a feature with which nonparametric methods do *not* distinguish themselves from parametric methods is that they make assumptions about sampling and distributions underlying the variable of interest. A critical assessment of the plausibility of assumptions is important for both nonparametric methods and parametric methods. An assumption both kinds of methods share is that samples are drawn at random. This assumption also underlies the Wilcoxon rank sum test. Another assumption of the Wilcoxon rank-sum test is that under the null hypothesis the observations in both study groups come from the same population distribution. The alternative hypothesis assumes that observations come from populations that are only different by a shift in location, but otherwise have the same shape and spread. If the latter assumption is unreasonable, the Wilcoxon rank-sum test produces a p -value that cannot be trusted.

The Wilcoxon rank-sum test for testing mean differences between three or more populations as in analysis of variance is available. A widely used test is the Kruskal-Wallis test (Kruskal and Wallis, 1952). Its technical discussion is beyond the scope of this article, but the basic idea is the same as for the Wilcoxon rank-sum test. One obtains for all respondents their rank in the combined samples, and then determines the rank sums per condition. Under the null hypothesis, we expect the same rank sums across all conditions. Variation in the rank sums across the groups suggests an effect. If the observed variance in the rank sums has a probability of exceedance smaller than 0.05 under the null hypothesis (i.e., $p < 0.05$), the effect is significant at the 5% level. The permutation test yields an exact p -value. Normal approximations exist as well; see Hollander and Wolfe (1999). Generalizations to multivariate analyses are possible (e.g., Katz and McSweeney, 1980; Finch and Davenport, 2009).

Measures of association and tests of independence for ordinal variables

The degree of association between variables, say, X and Y , provides information about either the underlying mechanisms of the phenomenon under study, or may be used to predict future events as in educational screening and for selection tests. Educational researchers may study whether motivation, home support, and access to learning materials are important variables for predicting study success. They may study the effect of a new teaching method on arithmetic ability or an operating educational policy on social inequalities. The most commonly used measure of association is Pearson's product-moment correlation (Pearson, 1895; also, see Agresti et al., 2017, Chap. 3), denoted ρ in the population, and r in the sample. Correlation ρ describes the degree of linear association between two variables. A correlation of 0 means absence of a *linear* association. Assuming bivariate normality for X and Y and a sample of size N , the null hypothesis that $\rho = 0$ can be tested using a t -test.

We assume that variables X and Y are ordinal, their relationship is non-linear, or that one is reluctant to assume bivariate normality, in each case rendering the product-moment correlation unsuitable. An alternative to the product-moment correlation is Spearman's rank correlation ρ_s (Spearman, 1904; also, see Liebetrau, 1983). The scores on each variable are replaced by their ranks, which we also denote X and Y . For example, for a respondent indexed i , the pair of ranks ($X_i = 7$, $Y_i = 15$) shows that (s) he was ranked 7 on variable X and 15 on variable Y . The difference between these ranks equals $d_i = y_i - x_i = 8$. We calculate the difference of the ranks for all other persons. When several people have the same score on a variable, they are put in random order, and their rank is the mean of the ranks assigned had no ties been observed. Thus, for each person i , we have converted their

scale-level measurements into scale-free and distribution-free rank numbers. Spearman's ρ_s is defined as the sample product-moment correlation between the rank numbers X and Y , and for sample data is denoted r_s . Ignoring ties for simplicity, and using differences d between paired ranks, r_s equals

$$r_s = 1 - \frac{6 \sum_{i=1}^N d_i^2}{N(N^2 - 1)}.$$

For small samples, a permutation test may be used for testing the null hypothesis that $\rho_s = 0$. Spearman's ρ_s is especially useful for studying associations between continuous variables that fail to meet the assumptions of bivariate normality. However, when X and Y are already discrete and ordinal, each with a limited number of categories, there will be many ties and Spearman's ρ_s may not be optimal. Kruskal's gamma (γ) and different versions of Kendall's τ are more appropriate (see [Hollander and Wolfe, 1999](#); [Liebetrau, 1983](#)).

Suppose an educational researcher investigates the association between students' satisfaction with school support and engagement in extracurricular activities. Perceived school support is measured using a three-point Likert item having ordered response categories *low*, *medium*, and *high*. Extra-curricular engagement is measured on a three-point scale having categories *never*, *occasionally*, and *often*. **Table 2** gives fictional data for this research question. Kruskal's γ and Kendall's τ coefficients use the concepts of concordant and discordant observation pairs to quantify ordinal association. A student who never engages in extracurricular activities and has low satisfaction and a student who often engages in such activities and has high school-support satisfaction form a concordant pair, because they are equally ordered on both variables. Hence, concordant pairs suggest positive association. Students ordered oppositely on the two variables form a discordant pair, suggesting a negative association. A tie occurs if a person pair has the same score on one or both variables. Ties allow different interpretations giving rise to different association measures.

Let C be the number of concordant pairs in the sample, D the number of discordant pairs, and T the number of ties. Kruskal's γ uses only C and D , and is defined as

$$\gamma = \frac{C - D}{C + D}.$$

Under the null hypotheses of independence we expect $C = D$, implying $\gamma = 0$. In the example in **Table 2** we have $C = 164$, $D = 26$, and $\gamma = 0.726$. Kruskal's γ treats ties as uninformative or undecisive about the association. [Kendall \(1938\)](#) took a different approach. Kendall's τ_a includes T and equals

$$\tau_a = \frac{C - D}{\frac{1}{2}[N(N - 1)]} = \frac{C - D}{C + D + T} \quad (1)$$

Kendall's τ_a is similar to gamma except that in the denominator it has all possible pairs that can be formed, including all possible ties. Conceptually, this means that ties provide evidence of a lack of association. Kendall's τ_b refines τ_a by making additional adjustments for the number of ties on each single variable. These ties are considered uninformative of the association and they are therefore subtracted from T in **Eq. (1)**. The resulting denominator contains all the relevant ordinal information available in the sample. Because T is reduced, we have $\tau_b \geq \tau_a$. In the example, we have $\tau_b = 0.512$. Kendall's τ_b is the preferred method when the ordinal variables have the same number of categories (i.e., the contingency table is square), otherwise, Stuart-Kendall's τ_c is preferred.

The γ and τ -coefficients can also be written as a function of the rank numbers, but the formulas are rather complex and therefore beyond the scope of this entry. What matters here is that the statistics use rank information and thus the permutation test may be used to test the association for significance. If the sample size permits, one can evaluate all possible permutations to derive the exact null distribution, but otherwise one could use the bootstrap method ([Davison and Hinkley, 1997](#)). Large sample approximations to the coefficients exist as well; see, for example, [Hollander and Wolfe \(1999, pp. 365–367\)](#).

Kruskal's γ and Kendall's τ_b are two of the many coefficients that are available; see [Liebetrau \(1983\)](#) for a review. These coefficients are so-called symmetric measures of association because their value does not depend on which variable is considered the dependent variable and which one is considered the independent variable. Sometimes, the researcher has a hypothesis about the causal mechanism underlying the association. Asymmetric measures of association, such as Somer's d ([Somers, 1962](#)), take on different values depending on which variable is the dependent variable and which one is the independent variable, and thus require articulated hypotheses of which of the two variables causally precedes the other.

Table 2 Fictional frequencies for student satisfaction with school support and engagement in extra-curricular activities.

Engagement in extra-curricular activities	Satisfaction with school support		
	Low	Medium	High
Never	4	2	0
Occasionally	2	8	3
Often	1	3	6

Miscellaneous methods

The methods discussed can be generalized in different ways. First, instead of comparing groups on a single outcome variable, one can compare them on a *combination* of several related outcome variables (e.g., [Pituch and Stevens, 2016](#)). For example, a researcher may study how different teaching methods influence student motivation using [Keller's \(2010\)](#) motivational design framework. Keller's model comprises four factors—attention, relevance, confidence, and satisfaction—that in combination invoke and maintain student motivation. Using a multivariate approach, one can test whether groups that received different teaching methods show significant differences in the combination (i.e., the profile) of these four aspects, and thus whether the teaching methods motivate students differently. If samples are small or modeling assumptions are violated, one may use a nonparametric approach to multivariate analysis of variance (MANOVA; e.g., [Puri and Sen, 1971](#)) to test between-group mean differences on multiple outcomes (i.e., H_0 : no mean differences; H_1 : mean difference on one or more outcomes). [Finch \(2005\)](#) showed that the nonparametric M-ANOVA has good statistical properties in situations in which the normality assumptions underlying the parametric MANOVA are violated.

Nonparametric data exploration for single variables

The first step in any statistical analysis should be inspecting the characteristics of the individual variables or pairs of variables. This enables researchers to make articulated decisions about subsequent statistical analyses, such as choosing between a nonparametric and parametric method. Furthermore, inspection may reveal anomalies such as outlying observations, out-of-range values, and missing data. Data screening involves descriptive statistics for central tendency, such as the mean, the mode, and the median, and spread, such as the variance, the range, and the interquartile-range. An important question is whether the data follow the normal distribution. The Shapiro–Wilk test is a well-known nonparametric test for evaluating whether the observations deviate from the normal curve. The Kolmogorov–Smirnov test is a more general, often-used nonparametric method for testing whether the data come from a hypothesized distribution, such as the normal. Often, it has less power than the Shapiro–Wilk test to detect violations of normality. Neither test makes assumptions about the population distribution of the data.

Data screening also involves graphs and other data visualization techniques. For example, the histogram is a simple nonparametric graphical method for inspecting the underlying distribution of continuous variables. A histogram is obtained by dividing the scale of the continuous variable into a finite number of consecutive non-overlapping intervals, also known as bins, and then counting the number of observations within each interval. [Fig. 2A](#) shows the histogram of reading proficiency for a sample of Dutch 15-year old children. The data were collected from the 2018 PISA study ([OECD, 2019](#)). The number and size of the bins govern

Fig. 2 Distribution of proficiency scores in a Dutch sample of 300 fifteen-year-old students using (A) the histogram and a small bin (B) the histogram and a wide bin; (C) a kernel smoother based on a small bandwidth; and (D) a kernel smoother based on a sufficiently large bandwidth.

the shape of the histogram. Small samples only allow a limited number of bins of which the height varies greatly, while some bins may be empty. Consequently, the histogram looks irregular, and gives an inaccurate impression of the underlying distribution. Reducing the number of bins yields a histogram that shows a more gradual pattern (see Fig. 2B), but has the risk that important local fluctuations will be obscured introducing bias. In practice, it may be difficult to find the bin size that optimally balances smoothness (i.e., absence of rapid local fluctuations) with accuracy.

Taking the study of a variable's distribution a step further, one may start with a fine-grained histogram and use a smoother to estimate the distribution (technically: the density) from a number of targeted focal points x_k ($k = 1, \dots, K$); see, for example, Silverman (1986) and Sheather and Jones (1991). The probability of each focal point is estimated using a weighted average of the bin to which the observation belongs and the neighboring bins, where the weights are defined by a kernel function. Kernel smoothing has the effect of bringing out the salient features of the distribution while filtering out irregularities that probably are due to sampling fluctuations. The degree of smoothness is controlled by the bandwidth-parameter, which determines the span of the neighboring observations, which are taken into account to estimate the probability of the focal point. A small bandwidth only gives weight to the observations close to the focal point, but a larger bandwidth also assigns weight to observations further away from the focal point, which results in a smoother curve. Fig. 2C and 2D show the smooth estimates of the distribution of proficiency scores obtained with kernel smoothing for small and large bandwidth, respectively. We discuss kernel smoothing, including the role of the bandwidth, in the next section.

Nonparametric regression models

Preliminary: parametric regression analyses

This section presents nonparametric regression analyses as an illustration of a more advanced nonparametric statistical method that allows researchers to study associations. Regression analysis (e.g., Fox, 2015) plays a prominent role in the social sciences. The basic model relates a single dependent variable, denoted Y , to one or more independent variables, denoted X_j ($j = 1, \dots, J$). The additive linear model is defined as

$$Y = \beta_0 + \sum_{j=1}^J \beta_j X_j + \varepsilon.$$

Coefficient β_0 is the intercept, coefficient β_j weights variable X_j , and ε is the residual representing the contribution of all neglected factors and random influences such as relevant independent variables, sampling errors and measurement errors. The model assumes that random influences cancel each other out, which implies that $E(\varepsilon) = 0$. As a result, the regression model is a model for the mean of Y conditional on the independent variables. Let $E(Y|X)$ be the expected mean dependent variable conditional on the independent variables collected in vector X , then the regression function $f(x)$ is defined as

$$f(x) \equiv E(Y|X) = \beta_0 + \sum_{j=1}^J \beta_j X_j. \quad (2)$$

The regression function in Eq. (2) also accommodates nominal or ordinal independent variables (Fox, 2015). Parameters β_j ($j = 1, \dots, J$) are of primary substantive interest. They express a partial effect, and their interpretation depends on the study design. Most often, cross-sectional data are used, and the effects have to be interpreted as follows: If two groups differ by one unit on independent variable X_j and are equal on the other independent variables, the expected mean difference in Y equals β_j . Frequently encountered interpretations like, "if X_j increases by one unit, Y is expect to increase by β_j units" are unwarranted if the regression model is fitted to cross-sectional data. For example, we may find in cross-sectional data a negative association between teacher's age and the use of new digital teaching tools. However, that does not mean that as teachers grow older, their use of digital tools will decrease. In fact, as the digitalization in education is growing fast, it is more likely that the use of digital tools will increase among all teachers. Cause-effect interpretations require at least an articulated causal diagram that describes the hypothesized causal processes, and the calculus of causation can then be used to decide whether the observed data allow consistent causal effect estimates (Pearl, 1996; Pearl and Mackenzie, 2019).

Hypotheses often tested are whether single variables contribute significantly to explaining variance in Y (i.e., $H_0: \beta_j = 0$ against $H_1: \beta_j \neq 0$), whether subsets of independent variables explain significant parts of the variance in Y (i.e., $H_0: \beta_j = \beta_k = 0$, against H_1 : "not H_0 "), and whether the amount of variance explained by the whole model, denoted R^2 , is significant (i.e., $H_0: R^2 = 0$ against $H_1: R^2 > 0$). For testing hypotheses about the regression coefficients or the explanatory power of the whole model, it is assumed (among others) that at all levels of X , the conditional distribution of Y is normal with mean 0, and has a constant variance; that is $\sigma_{\varepsilon|x}^2 = \sigma_{\varepsilon}^2$. This assumption is known as homoscedasticity. By implication we assume $\varepsilon \sim N(0, \sigma^2)$, where σ^2 is the marginal variance of the residuals.

Let e_ν be the observed residual for person ν under the estimated model. The estimated residual variance ($\hat{\sigma}^2$) equals $\frac{\sum_{\nu} e_\nu^2}{(N-K-1)}$, where K is the number of estimated regression weights β_j ($j \geq 1$). Variance $\hat{\sigma}^2$ is the pooled estimate of the conditional variances $\sigma_{\varepsilon|x}^2$. If the assumption of homoscedasticity is violated, the use of the pooled estimate $\hat{\sigma}^2$ for hypothesis testing is no longer valid,

and alternatives, such as weighted-least-squares regression should be considered (Fox, 2015). Variance $\hat{\sigma}^2$ is also invalid if there is systematic misfit due to model misspecification, for example, when fitting a linear model to data when a curvilinear relationship would be in order.

Nonparametric regression analysis

Suppose, the researcher has insufficient evidence supporting linearity, normality, and homoscedasticity, or that his/her substantive theory does not imply this degree of structure. Then, nonparametric regression methods provide an alternative for studying the relationships between variables. The terminology of nonparametric pertains to two different aspects. First, one refrains from postulating a parametric regression function $f(x)$, as in Eq. (2), but instead estimates the functional form directly from the data. Data-driven estimates of the functional form provide interesting information about relationships that may otherwise remain concealed by a priori assuming a parametric form. Second, when the assumptions about the distribution of the residuals ε are incorrect, one may use nonparametric methods to test hypotheses about the regression parameters.

For simplicity, we consider models with one explanatory variable, X . For didactic reasons we use an artificially created data set to illustrate concepts and methods. To give some context to the results, we pretend that the data concern children's age (X) and intelligence (Y). Fig. 3A shows the scatterplot. The straight solid line is the least-squares estimate of the linear regression function. In this

Fig. 3 Examples of different smoothers using fictional educational data: (A) the linear model; (B) binning using a large bandwidth; (C) kernel smoothing using a small bandwidth; (D) kernel smoothing using a larger bandwidth; (E) spline smoother with no roughness penalty; (F) spline smoother with a roughness penalty of 1.

example, a linear model does not describe the relationship between age and test scores well. To improve the fit of the model to the data, one could estimate a polynomial function that includes higher-order terms such as X^2 and even X^3 , but that did not yield an adequate fit either. This lack of fit for polynomial models is a common finding (e.g., Fan and Gijbels, 1996). Fan and Gijbels (1996; see also Fox (2015, p. 511) pointed out that to achieve adequate fit using polynomial functions one often needs a high-degree polynomial, which results in large variability of the parameters and unstable results, as well as unpredictable behavior of $f(x)$ for X values remote from the bulk of the predictor values.

If one cannot or is not prepared to assume a specific parametric form for the regression function, the simplest alternative is to compute the mean Y conditional on separate values of X , which we will denote by $\bar{Y}|x$, and then draw the graph that connects adjacent conditional estimates $\bar{Y}|x$. Problems similar to computing histograms may arise when only few values of Y are tied to separate values of X . Bins may solve this problem, similar to the computation of histograms. Let the bins be indexed by $k = 1, \dots, K$ and let $\bar{Y}|k$ denote the mean of all observations within the k th bin. The triangles in Fig. 3B give the local estimates for seven bins, each bin spanning a one-year age-range. The connected solid line is the estimated regression function. The nonparametric estimate better describes the trend and thus has better fit than the linear model in Fig. 3A.

Binning is simple, but the categorization of the independent variable into non-overlapping categories makes it inefficient. An improvement is to use a moving local average. Let x_0 be a point on the X -scale and let $E(Y|x_0)$ be the unknown conditional mean for which we seek the best possible estimate based on the data; that is, $E(Y|x_0)$ is the value of the intended regression function f at point x_0 . The moving average, also known as nearest-neighbor smoother, takes the m nearest values to x_0 and takes the average of these neighbors as the estimate $\hat{f}(x_0)$; that is, $\hat{f}(x_0) = \frac{\sum_{i=1}^N d_i y_i}{\sum_{i=1}^N d_i}$, where $d_i = 1$ if x_i belongs to the m nearest neighbors, and 0 otherwise.

Kernel smoothing takes local averaging a step further by assigning weights to observations that are greater the closer the observation is to the focal point x_0 . Denoting weights by w_i , the locally weighted average is obtained as

$$\hat{f}(x_0) = \frac{\sum_{i=1}^N w_i y_i}{\sum_{i=1}^N w_i}, \quad (3)$$

where the weights w_i are defined by the kernel function that uses the distance of x_i to the focal point x_0 . Eq. (3) is the Nadaraya-Watson estimator (Fan and Gijbels, 1996). Among the most frequently used kernel functions are the Epanechnikov and the Gaussian, because of their efficiency and their sound theoretical basis. The Epanechnikov kernel defines the weights w_i using a parabolic function centered around x_0 . The Gaussian kernel is defined as the bell-shaped curve

$$K(x_i, x_0) = \exp \left[\frac{-(x_i - x_0)^2}{\lambda} \right]. \quad (4)$$

The critical factor in kernel smoothing is the choice of the bandwidth parameter λ that determines the width and with that the steepness of the bell-shape. As the curve is narrower, it is also steeper and only data points close to the focal point are effective in estimating $f(x_0)$. Fig. 3C shows the estimated regression function using Gaussian-kernel smoothing for a small bandwidth. The resulting curve shows an erratic trend, which is due to the use of few data points for each estimate of the regression model. Fig. 3D shows the curve for a (sufficiently) large bandwidth, showing that as λ increases, the estimated regression curve gets smoother, but also flatter and less informative about the general trend. This is due to the use of both data points that are close and data points much further away from the focal point, so that estimates for different focal point are rather similar.

The examples show that there is a trade-off between (local) accuracy and precision, also known as the bias-variance trade-off. Choosing the bandwidth is somewhat arbitrary and difficult, because one wants to avoid capitalizing on random fluctuation (small bandwidth), while preventing potentially interesting trends from being obscured (large bandwidth). Automated procedures for selecting the optimal bandwidth exist, but we advise not to rely solely on automated procedures because the optimal *statistical* solution may not always be the optimal *substantive* solution for the application envisaged (e.g., Fox, 2015, p. 534; also Sheather and Jones, 1991). Instead, we recommend trying different bandwidths and visually decide which bandwidth value constitutes the tipping point where the regression function changes from a sufficiently smooth function to a function too erratic. The automated bandwidth may be a good starting point. For more in depth discussions on bandwidth selection, see Fox (2015, Chap. 18) and Loader (1999, Chap. 10).

Advanced smoothers

Kernel smoothers are local-constant fit methods. They are flexible, easy to implement, but also have some drawbacks (Fan and Gijbels, 1996; Fox, 2015). First, they tend to suffer from end-point bias. This means that the estimated regression curve may be biased for x -values at the boundaries of the observed X domain, because only neighboring data points on one side of the focal point are available. Second, local constant fit methods ignore the local shape of the regression function around x_0 , rendering the method less efficient and less accurate. To overcome these drawbacks, local-linear or local-polynomial regression smoothers may be used (e.g., Fan, 1993; Fox, 2015). The method assumes that a k -order polynomial regression model accurately describes the local trend

in the data. In particular, for each focal point x_0 , we estimate a polynomial regression function using weighted least-squares; that is, we find parameters β_0 and β_m ($m = 1, \dots, k$) in

$$\hat{Y} = \beta_0 + \sum_{m=1}^k \beta_m (X - x_0)^m,$$

that minimize $\sum_{i=1}^I w_i (Y - \hat{Y})^2$, where w_i is the kernel function of interest such as the Gaussian kernel (Eq. 4). Parameter estimate $\hat{\beta}_0$ is the estimated focal function value; that is, $\hat{f}(x_0) = \hat{\beta}_0$. The estimates for a carefully selected series of focal points provide the estimated regression curve. Research has shown that the local linear smoother (i.e., $k = 1$) already greatly improves local-constant kernel smoothing (Fan, 1993). We see this, for example, when the regression function around x_0 is linear, but the observations x are not symmetrically distributed around the x_0 . The local-constant is biased, but not the local-linear smoother (Fox, 2015, pp. 536–537).

Kernel smoothing and local-polynomial regression are two of many smoothing techniques that are available. They construct the regression function using locally weighted averages for a series of focal points x_0 . The resulting regression function is obtained using linear interpolation between these discrete points. The bandwidth parameter, the choice of the focal points, and the kernel function together govern the degree of smoothness. Although effective in studying trends in the data, the methods do not guarantee that the regression function is smooth and continuous everywhere along the X -domain. Piece-wise spline regression and spline smoothing (De Boor, 2001; Green and Silverman, 1994; Marsh and Cormier, 2002; Ramsay and Silverman, 1997) produce smooth and continuous regression functions.

First we consider *piece-wise spline regression*. Suppose we have N distinct observations (x_i, y_i) without ties on either x or y , which are grouped into K bins. One can estimate a regression function in each bin such that the curves in adjacent bins connect smoothly. Not only should curves from adjacent bins connect the points on the boundaries of the bins, also called knots, but in passing a knot, the slope of the curve should not change abruptly. This desired property requires at least a cubic polynomial function in each bin, so-called cubic splines. The result of all K splines is a continuous regression function, which can be uniquely defined by the function value and the second derivative at each scale point x . The number of bins and the location of the knots determine the level of smoothness.

Spline smoothing does not rely on binning, but solves the smoothness problem at the knots by putting a penalty on the “roughness” of the function. In particular, let $f''(x)$ be the second derivative of (x) . The penalized spline smoother determine the function f by minimizing

$$\sum_i [y_i - f(x_i)]^2 - \alpha \int_{x_{\min}}^{x_{\max}} f''(x)^2 dx$$

where $\alpha > 0$.

The integral $\int_x f''(x)^2 dx$ describes the roughness and parameter α expresses the desired balance between fit and degree of roughness. If $\alpha = 0$, the function is a piece-wise cubic polynomial function between adjacent x -values. It has maximum fit as it is as close to the data as possible, but shows many rapid local fluctuations as in Fig. 3E. As α increases, the function f converges to a straight line. Fig. 3F shows the curve based on the same data for an appropriate roughness penalty. Spline smoothing is a particular case of a general class of penalized optimization methods having advantageous properties. It does not require binning uses a parameter directly linked to the roughness of the estimated function, and tends to be less sensitive to end-point bias.

Order-restricted nonparametric regression

The methods discussed do not impose restrictions on the form of the regression function. They are useful descriptive tools to inform the researcher about possible relationships in the data. However, a researcher may have a priori hypotheses about the shape of the relationship. For example, when studying educational progress, it may be reasonable to assume a monotone progression in the development of children’s cognitive abilities. To test this hypothesis, one may fit a regression model that is monotonically increasing; that is, for every pair of predictor values $x_1 < x_2$, the researcher expects $\hat{f}(x_1) \leq \hat{f}(x_2)$. Using the unconstrained model as the baseline model (i.e., the full model), one can test whether the restricted model describes the data equally well as an unconstrained model. In other words, whether imposing restrictions does not lead to a model having significantly worse fit. Order-restricted regression methods have a long history (e.g., Barlow et al., 1972). Developments that are more recent include Dette et al. (2006), whose approach results in a strictly increasing function. Other approaches to constrained regression methods include monotone spline smoothing (e.g., Green and Silverman, 1994; Ramsay, 1988).

Exploring the relationship between variables is often just the first step in educational research. The ultimate goal is to answer questions about the interplay between several variables, which leads to a better understanding of teaching methods, learning strategies, and the effectiveness of educational policies. Nonparametric regression is available for multivariate data (i.e., multiple regression) and for different types of outcome variables (e.g., ordinal indicators, binary outcomes; Fox, 2015). For example, if we have two independent variables, instead of estimating a line, multivariate models estimate a smooth plane through the data points (x_1, x_2, y) . Furthermore, we can evaluate how much each single independent variable contributes to the explained variance, and use

hierarchical regression analysis to test the contribution for significance. Spline smoothing accommodates hybrid approaches, in which, for example, one independent variable is modeled using a spline smoother, and the others using a linear model. The contribution of each single independent predictor can be evaluated using their contribution to the penalized sums of squared residuals.

Gauging uncertainties: nonparametric confidence intervals

Sample statistics provide uncertain information about parameters. This uncertainty has to be taken into account to fully appreciate the results of empirical studies. Inferential statistics addresses the question to what extent similar results would be found if the study was replicated using a new sample. Uncertainty is quantified using standard errors. They express the degree of variability in the sample statistic because of sampling errors. Parametric models derive a statistic's standard error assuming that the sampling distribution follows a parametric distribution, such as the normal. For the mean, the assumption is justified by the central limit theorem, which states that if the sample size is sufficiently large (say, >25) the distribution of sample means based on random samples of the same size approximates the normal distribution. Let s denote the sample standard deviation and $\bar{X}$ the sample mean, then the standard error equals $s_{\bar{X}} \approx s_X / \sqrt{n}$. If samples are small or the normal approximation does not apply, asymptotically derived standard errors are biased and nonparametric methods may be in order. An example is the nonparametric bootstrap (e.g., [Efron and Tibshirani, 1993](#)).

The starting point for bootstrapping is the assumption that the sample is representative of the target population. Using computer technology, we create a new data set by resampling—that is, repeatedly drawing a sample—of N observations, with replacement, from the data set. Because the observations are sampled with replacement, the newly simulated data set likely contains several original observations more than once and will be different from the original data set. Thus, sample statistics will also be somewhat different and vary across samples. By repeating this process, say 1000 times, we obtain 1000 simulated data sets. The standard deviation of the test statistic across the 1000 data sets is our standard error. This idea can easily be extended to more complex situations, including nonparametric regression methods. The data set consists of N pairs of scores (x_i, y_i) . Using resampling with replacement, we construct simulated samples of pairs (x_i, y_i) and fit the nonparametric regression curve to each simulated data set. It is imperative that one uses the same focal points and the same bandwidth parameters. At each focal data point x_0 , the fifth and ninety-fifth quantile can be determined, producing a confidence envelope (to be illustrated in the next section).

Nonparametric bootstrapping is easy to implement, but [Davison and Hinkley \(1997\)](#) explain that bootstrap methods should be used carefully, and not as an escape for inadequate sampling designs, failed data collections, or inappropriate study designs. Moreover, as is true for all standard errors, nonparametric bootstrapping results are sensitive to sampling errors themselves; that is, anything we compute from a sample is liable to uncertainty. For example, if we take a small sample from the population, and by coincidence, the sample is homogeneous, then the nonparametric bootstrap standard errors may be too small, suggesting more certainty than is justified. In addition to the nonparametric bootstrap, parametric bootstrap also exists ([Davison and Hinkley, 1997](#); [Efron and Tibshirani, 1993](#)). The parametric bootstrap generates simulated data sets using a statistical model.

Illustration using PISA data

As an example of data analysis using nonparametric statistics, we consider measurements of reading proficiency from the PISA project and additional data on students' attitude toward reading. Students were asked to express whether they think reading is a waste of time on a four-points Likert scale ranging from strongly disagree ($=1$) to strongly agree ($=4$). For convenience of interpretation, we have reverse-scored this variable so that a higher score indicates a more positive attitude toward reading. [Fig. 4A](#) shows the raw data for a random sample of 500 students. Clearly, the linear model is inappropriate here. Alternatively, an ordinal logistic model (e.g., [Fox, 2015](#), Chap. 14) might be considered, but logistic models assume linearity at the logit scale and are still restrictive. Nonparametric methods are good candidates in this case for studying the relation between interval-level independent variables and an ordinal-polytomous response variable.

We used spline smoothing to model mean attitude toward reading as a function of reading proficiency. Spline smoothing captures nonlinear trends, and does not force the lower and upper asymptotes equal to the minimum item score and maximum item score, respectively. [Fig. 4B](#) shows the estimated regression function along with the bootstrapped 90% confidence bands for another subsample of 700 respondents. Notice that the regression function gives the expected item score as a function of reading proficiency. For low levels of proficiency, there is only a weak relation with attitude toward reading. However, for reading proficiency of 350 or higher, the relationship is positive. The confidence bands suggest that the trend is real and not caused entirely by sampling fluctuation.

Concluding remarks

Nonparametric methods are appropriate when certain assumptions about variable distributions are questionable and sample sizes are small. These advantages render their use especially appealing in studies where large samples are not feasible, such as studies that involve expensive experimental equipment (e.g., virtual reality glasses) or studies that require intensive data gathering procedures

Fig. 4 Empirical example of the nonparametric regression approach to study the relation between a continuous independent variable and a categorical dependent variable having four ordered response categories.

(e.g., using think-aloud methods). Nonparametric statistical methods are also useful in preliminary research on the possible effectiveness of new educational methods at a small scale. Using non-parametric methods, and perhaps a liberal alpha level (e.g., $\alpha = 0.10$, or $\alpha = 0.20$) to reduce the chance of committing type II error (i.e., falsely rejecting an effective method), often gives a good first impression of the possible effectiveness of the new method envisaged but making as few assumptions as possible. Researchers can use this information to refine the subsequent large-scale study further.

This entry also discussed several exploratory data-driven techniques (smoothers) to study relations between variables. With that, we are also connecting to the growing field of artificial intelligence (AI) and related machine learning methods. AI has become popular in many social and scientific areas. For example, companies use data-driven exploratory techniques to uncover patterns in consumer behavior and use the knowledge they acquire to recommend products that are attractive to individual consumers. These companies usually have large amounts of data at their disposal. To take full advantage of the information in the data, they prefer starting their analyses with as few assumptions as possible rendering non-parametric modeling techniques as a perfect basis. Education shows similar trends. Due to the increasing use of computers and smart devices (e.g., tablets, smart phones, virtual reality) in the classroom, increasingly richer data become available for educational purposes. This trend led to a fast growing field of learning analytics and personalized learning, in which “smart” learning algorithms are used to tailor the instructions to the specific needs of the student. Flexible self-learning models are needed to support students optimally and nonparametric methods are excellent candidates to realize this goal.

Machine learning methods put a strong emphasis on data exploration and prediction. Cross-validation techniques are used to validate the model and to evaluate the precision of predictions in the future. Prediction-based modeling certainly also has its benefit in an educational context, but caution has to be exercised when adopting such techniques in high-stakes educational settings. Uncritical use of prediction models without a solid theoretical basis may, for example, perpetuate educational disadvantages. When it comes to important high-stakes decisions, such as assigning students to special education or certification, it is imperative to also *understand* why and how certain trends in the data emerge. This goal can only be achieved from carefully designed studies, driven by theoretically sound and articulated hypotheses and using carefully selected samples, and using appropriate statistical tools that do justice to the characteristics of the underlying data. The nonparametric methods presented in this entry serve this goal.

Introduction

Identifying causal effects is critical to educational research and practice, because many questions in education concern causal relationships between interventions and (un)intended outcomes. Does repeating a grade help struggling learners in early grades, or is retention harmful to students in the long run? Do investments in private charter schools pay off in terms of improved outcomes in students and communities? Do gifted learning programs in public schools help students achieve future successes, or do they widen socioeconomic and racial disparities? Despite their importance and prevalence, the causal impacts of interventions, or treatments, can be difficult to identify in practice. The difficulty stems from each unit being observable in only either the treatment or the control condition, but never in both conditions simultaneously. For example, a student can either repeat a grade or advance to the next grade, but they cannot experience both. This so-called “fundamental problem of causal inference” (Holland, 1986) precludes simply calculating each unit’s causal effect as the difference between their treated and control outcomes, thereby necessitating assumptions to estimate causal impacts.

Randomized experiments are considered the ideal study design for causal inference but are often unethical or impractical to implement in many educational settings. Therefore, answering causal questions requires subject-matter knowledge surrounding a particular context. Assumptions are inevitably made and incorporated into research designs and analytic techniques for estimating the impacts of treatment while accounting for threats such as selection bias, omitted variables, and measurement error. This article aims to provide the fundamental concepts, issues, and analytic tools that can be used to draw causal inferences in education and more broadly in the social sciences. An added complication is that clustered or multilevel data are common in educational research, as students are generally nested within classes and schools, and thus units within clusters are often dependent. Challenges and strategies with multilevel data are described throughout the article in the context of causal models.

The rest of the article is structured as follows: **Articulating causal effects using potential outcomes** defines the causal effect of a treatment on an outcome using the potential outcomes framework, and explains core assumptions for identifying and estimating average treatment effects, such as the *stable unit treatment value assumption*, also known by its acronym SUTVA (Rubin, 1986), and *unconfoundedness*. **Determining which covariates generate confounding of treatment and outcome** presents *causal diagrams*, also referred to as *causal graphs* or *directed acyclic graphs (DAGs)*, that facilitate intuitive graphical representations of causal relations between variables grounded in theory. Causal diagrams grounded in established theory and empirical evidence can enhance understanding of underlying causal mechanisms, and improve subsequent causal inferences. In particular, they can be an essential research tool for determining which covariates should (not) be adjusted for when seeking an unbiased estimate of the causal effect. We provide examples of simple causal diagrams involving various variables, such as *confounders*, *mediators*, and *colliders*, and explain why it is important to distinguish between these different types of variables. **Estimation of causal effects when unconfoundedness can be established** reviews widely used analytic techniques for estimating treatment effects, such as covariate adjustment, *propensity scores*, and other *matching* techniques, as well as combinations of treatment selection and outcome models, and their modifications and extensions to multilevel data. Because the aforementioned estimation methods rely on the unconfoundedness assumption, we describe sensitivity analyses for assessing how different causal inferences can be due to unmeasured confounding. **Estimating causal effects when unconfoundedness is precluded** describes an example of natural experiments called *instrumental variables* for estimating causal effects when unconfoundedness cannot be reasonably assumed to hold. The final section summarizes the major concepts discussed in the article and concludes with recent advances in causal modeling. Relevant references and suggested further readings are provided throughout the article.

Articulating causal effects using potential outcomes

Suppose that research interest is in whether education in a private high school leads to higher academic achievement scores than education in a public high school. Such causal questions can be readily and precisely formalized using the *potential outcomes* framework, commonly referred to as the Neyman-Rubin Causal Model (Splawa-Neyman et al., 1990; Rubin, 1990). The framework encourages conceptualizing and explicating the cause-effect relation in terms of well-defined treatment and control conditions, e.g., education in either a private or a public high school; and the outcome of interest, e.g., math, reading, or vocabulary scores. The potential outcome of each student can then be defined as the outcome that would have been observed had that student been, possibly contrary to actuality, enrolled in either treatment or control (Rubin et al., 2004). Precise articulation of treatment and control conditions is thus essential to ensure that these potential outcomes exist and are well-defined for all members of the population of interest. For example, let Z denote a student's enrollment in either a private ($Z = 0$) or public ($Z = 1$) high school, and let Y denote an academic outcome such as their reading comprehension score. Let $Y(0)$ and $Y(1)$ denote their potential outcomes had they been enrolled in a private and public high school, respectively. Hence, it must be conceptually conceivable that each student in the population of interest could be enrolled in either a private or a public high school. We will be agnostic to the philosophical debate over, and metaphysical nature of, causation and instead refer interested readers to Morgan and Winship (2015) and Pearl and MacKenzie (2018).

Hypothetically, if the values of both potential outcomes for each student were available for analysis, each student's individual treatment effect can be determined simply as a contrast between the potential outcomes. For example, the individual treatment effect of education in a public versus private high school for each student (on the additive scale) is the difference $Y(1) - Y(0)$. The corresponding average treatment effect (ATE) across all students in the population would then be the population expectation of the individual treatment effects, i.e., $E[Y(1) - Y(0)]$. However, because exactly one of these potential outcomes can be observed for each student, depending on their observed treatment, the unobservable potential outcome exists as a counterfactual (Pearl, 2010). In other words, the observed outcome can be determined from the potential outcomes and the observed treatment as $Y = Y(0)(1 - Z) + Y(1)Z$. Thus, a cornerstone of the potential outcomes framework is the maintenance of an assumption known as the stable unit treatment value assumption (SUTVA) (Rubin, 1986). SUTVA is a basic assumption of causal effect stability that requires (i) the treatment and control conditions to be well-defined so that there are "no hidden treatment variations" among individuals experiencing the same condition, and (ii) each individual's potential outcomes to be unaffected by treatments experienced by other individuals so that there is "no (treatment) interference" (Imbens and Rubin, 2015). As discussed in Hong and Raudenbush (2006), SUTVA becomes more challenging in multilevel data because of the intrinsic dependency within clusters and potential peer or spillover effects. We review recent advances under such settings in a later section.

When treatment is randomized, routine statistical methods comparing the outcomes between treated and control individuals can be used to estimate the average treatment effect. The estimate is unbiased for the causal impact of treatment in the population of interest, regardless of the result from a null hypothesis test of no treatment effect. Random assignment is desirable for causal inference because it renders the treatment and control groups equal in expectation on all observed and unobserved dimensions except for the treatment status. A thoughtfully designed and properly conducted randomized experiment ensures that all competing explanations for any differences in the observed outcomes between the treatment and control conditions are disavowed. A treatment assignment mechanism is therefore termed as being *unconfounded* when the observed condition to which a participant is assigned possesses no information about their potential outcome under the unobserved condition.

When treatment is not randomly assigned, a more involved approach that carefully adjusts for common causes of both treatment and outcome is required to estimate the causal effect without bias. Continuing the example above, any differences in academic outcomes when comparing students in private and public schools are likely not due to the choice by itself causing the outcomes, but rather due to the (unmeasured) resources that are available to students who are more likely to enroll in a private school, and thus obtain better outcomes. For example, private school students may be economically advantaged to pay the tuition required in private schools, and experience more engaging environments for learning outside of school. Hence in observational studies where individuals can select their experienced treatment, non-causal (or "spurious") correlations between the treatment and outcome can arise, due to their mutual associations with such confounders. When these confounders are not adjusted for, because they were either unmeasured, or measured but excluded from the analysis, they induce confounding bias in the treatment effect estimate. Let L denote a determined subset of covariates that generate confounding of the treatment-outcome relation. The unconfoundedness assumption states that the probability of selecting either treatment or control is independent of the joint potential outcomes (and any function of them), within strata defined by all combinations of values of L . When all confounders L are measured and this assumption is plausibly satisfied, individuals with the same values of L are equally likely to have selected treatment (also termed "comparable" or "exchangeable") regardless of their observed treatment status, so that treatment is effectively randomized within strata defined by L . Confounding is therefore a causal concept that does not apply when simply assessing statistical correlations (Hernán and Robins, 2020). The *positivity* assumption further states that conditional on L , the probabilities of selecting treatment, and selecting control, are both non-zero; i.e., $0 < \Pr(Z = 1|L = l) < 1$ for all unique values of $L = l$. We describe in the next section how researchers may use theoretical knowledge and prior empirical evidence to determine which covariates associated with treatment, outcome, or both treatment and outcome, are appropriate for adjustment to eliminate confounding bias.

Determining which covariates generate confounding of treatment and outcome

When treatment is non-randomized, covariates that generate confounding of the treatment-outcome relation must be adjusted for to eliminate as much spurious correlation as possible from the causal effect estimate. But routinely including all measured variables that covary with either treatment, or outcome, or both, in the analysis can yield biased estimates. Therefore, determining whether to adjust for a particular covariate when assessing the causal effect requires carefully considering the causal relations between the covariate and treatment, and between the covariate and outcome. The causal diagram approach to causality (Pearl, 2009, 2012) is invaluable for visualizing and explicitly evaluating such causal relations. Causal diagrams that accurately represent data-generating processes can provide clear justifications for systematically determining which covariates must be adjusted for to eliminate non-causal associations when estimating the causal effect (Elwert, 2013). Causal diagrams are particularly appealing because they resemble traditional path diagrams in social science research (Pearl, 1998; Bollen and Pearl, 2013). However, causal diagrams encode causal relationships that are completely nonparametric. Unlike path diagrams, it is unnecessary to specify the nature of the functional dependence of each variable on its causally antecedent variables. Furthermore, causal diagrams are drawn based on extant subject matter theory and prior empirical evidence, whereas path diagrams are (often) drawn based on the observed data.

We briefly introduce basic terminology and features of causal diagrams using simple examples. In each example we will focus on a single covariate and its causal relations with treatment and outcome. Variables are represented in a causal diagram using nodes. For example, in the causal diagrams shown in Fig. 1, we will use the node Z to represent treatment, and the node Y to represent outcome. The directed *edge* (i.e., single-headed arrow) from one node to another symbolizes a causal effect that the variable at the origin exerts on the variable at the terminus. For example, in the causal diagrams shown in Fig. 1, the arrow from Z to Y depicts the causal effect exerted by treatment Z on outcome Y . The presence of an arrow merely represents a causal effect of an unknown magnitude, whereas the absence of an arrow precludes any possible causal effect. A *path* is any sequence of edges pointing in any direction that connects one variable to another, with no recurring variable on that path. For example, in the causal diagram of Fig. 1a, the path $Z \leftarrow L \rightarrow Y$ links treatment Z and outcome Y via a shared common cause L . In general, any path with one arrow pointing to treatment, and another pointing to outcome, is termed a “back-door” path from treatment to outcome.

When the confounder L is unadjusted for in the analysis, its absence will generate a non-causal (or spurious) empirical association between Z and Y that induces bias in the causal effect estimate. In other words, adjusting for L “blocks” the path between Z and Y so that the causal effect of Z on Y can be estimated without bias; see e.g., Hayduk et al. (2003). However, confounders are not necessarily direct causes of both treatment and outcome. Consider the causal diagrams in Figs. 1b and 1c, where L is associated with either Z due to an unmeasured common cause U_{Lz} , or Y due to an unmeasured common cause U_{Ly} , respectively. Even though L causally influences only either Z or Y , failing to adjust for L will lead to a spurious association between Z and Y . Therefore, the back-door paths between Z and Y can be blocked by adjusting for L , even when U_{Lz} or U_{Ly} are unmeasured and cannot be adjusted for. In all three scenarios presented in Figs. 1a to 1c, it is appropriate (and recommended) to adjust for the confounders L .

We now turn to other covariates that may be associated with both treatment and outcome. A *directed path* is a path in which all edges point in the same direction. For example, in Fig. 1d, $Z \rightarrow M \rightarrow Y$ is a directed path from treatment to outcome that intersects the intermediate variable M , commonly referred to as a *mediator*. Notwithstanding M being associated with both Z and Y , M does not lie on a back-door path from Z to Y , and should not be adjusted for. It is only appropriate to adjust for M when interest is in the so-called “direct effect” of Z on Y transmitted via causal pathways that do not intersect M . Evaluating the treatment effect transmitted along directed paths intersecting possible mediator(s) is the focus of (causal) *mediation analyses* that seek to partition the treatment effect into direct and indirect components. Otherwise, M should be unadjusted for when assessing the (“total”) effect of Z on Y via all possible causal pathways leading from Z to Y .

A variable is a *collider* along a particular path if it has two arrows pointing directly at it. For example, in the causal diagram of Fig. 1e, C is a collider along the path $Z \rightarrow C \leftarrow Y$. An unadjusted collider blocks a path so that there are no non-causal associations between the origin and terminus along that path. However, adjusting for a collider, such as the common effect C of both Z and Y , will create a spurious correlation between Z and Y . Hence C should not be adjusted for when estimating the causal effect of Z on Y . It is important to note that C need not be directly caused by both Z and Y , as shown in Figs. 1f and 1g, for C to be a collider along a path between Z and Y . For example, even when C is merely associated with Z due to an unmeasured common cause U_{Cz} , C is nonetheless a collider along the path $Z \leftarrow U_{Cz} \rightarrow C \leftarrow Y$. Additionally, when C is merely associated with Y due to an unmeasured common cause U_{Cy} , C is a collider along the path $Z \leftarrow U_{Cz} \rightarrow C \leftarrow U_{Cy} \rightarrow Y$. Adjusting for C induces “collider (stratification) bias,” and colliders should thus remain unadjusted for (Greenland, 2003b; Cole et al., 2009; Ding and Miratrix, 2015; Thoemmes, 2015). Note that the causal diagrams in Figs. 1b and 1f differ only in whether Y is an effect of L , or a cause of C , respectively. The direction of the causal effect thus determines whether to adjust for the covariate, or not. A variable is a *descendant* of another variable if it can be reached by a directed path. For example, in the causal diagram of Fig. 1h, D is a descendant of C . No collider (nor any descendant of a collider) along a causal path from Z to Y should be adjusted for, otherwise it can create spurious correlations between treatment and outcome that induce bias in the effect estimate.

It may therefore be tempting to simply rule out adjusting for all variables—besides outcome—that are measured temporally after treatment, but it is important to note that such variables need not be causally influenced by treatment. For example, in Fig. 1b, if L shares a common cause U_{Lz} with Z , such as when L and Z are different measures of the same underlying latent

Causal diagram	Whether a covariate should or should not be adjusted for
a 	Confounders L that are common causes of Z and Y must be adjusted for.
b 	Confounders L that causally influence Y , but are only associated with Z due to an unmeasured common cause U_{lz} , must be adjusted for.
c 	Confounders L that causally influence Z , but are only associated with Y due to an unmeasured common cause U_{ly} , must be adjusted for.
d 	Intermediate variables M on a causal path from Z to Y should not be adjusted for when estimating the (total) effect of Z on Y via all possible causal paths.
e 	C is a collider on a path from Z to Y , and should not be adjusted for.
f 	C is a collider on a path from Z to Y (with U_{cz} being unmeasured), and should not be adjusted for. Another possibility for C to be a collider on a path from Z to Y is if U_{cy} is an unmeasured common cause of C and Y , and Z causally influences C instead.
g 	C is a collider on a path from Z to Y (with U_{cz} and U_{cy} both being unmeasured), even though C is not a causal descendant of either Z or Y , and thus should not be adjusted for. Bias resulting from adjusting for C is variously referred to as “collider (stratification) bias,” “included variable bias,” or “M-bias.”
h 	D is a descendant of a collider C along a path from Z to Y , and should not be adjusted for, regardless of whether C is adjusted for or not.
i 	A affects only Z , and is unassociated with Y , and thus should not be adjusted for. When identifying the causal effect of Z on Y is prohibited by the unmeasured confounder U_{zy} , A can act as an instrumental variable to facilitate estimating the effect of Z on Y under certain assumptions.

Fig. 1 Causal diagrams describing examples of causal relations between a third observed variable with treatment Z and outcome Y . Confounders are denoted by L , mediators are denoted by M , colliders are denoted by C , and instruments are denoted by A . Rectangular nodes denote observed variables, while round nodes denote unmeasured variables.

construct U_{lz} , then L should be adjusted for even if it is measured after treatment Z is recorded (and a causal effect of Z on L can be precluded). Therefore, the causal influence of treatment on such “post-treatment” or “treatment-induced” variables, such as M , C or D , must be grounded in established theoretical knowledge or prior thoughtful experimentation. Finally, we consider the setting depicted in the causal diagram of **Fig. 1i** where the variable A causes Z but does not causally influence Y directly.

Instrumental variables such as A should not be adjusted for when estimating the causal effect of Z on Y because they produce inefficient estimators without reducing confounding bias (Brookhart et al., 2006; Wooldridge, 2016). When an unmeasured confounder U_{zy} precludes blocking the back-door path $Z \leftarrow U_{zy} \rightarrow Y$, the instrumental variable A permits causal inference under certain scenarios. We discuss this in a later section.

Mediators M , colliders C , descendants of colliders D , and instrumental variables A are examples of covariates that must be handled cautiously when carrying out confounding adjustment; see Pearl (2013) for further details on their impacts on confounding bias. A causal diagram containing all the (un)observed variables in a study can be constructed by starting with the treatment-outcome causal relation, then adding covariate nodes and arrows based on relevant existing literature and procured expert knowledge. A causal diagram that accurately represents structural relations grounded in established theory can improve understanding and reasoning of underlying causal mechanisms (Elwert, 2013; Morgan and Winship, 2015; Rohrer, 2018; Grosz et al., 2020).

When more complex causal relations among the covariates are known, all possible back-door paths between treatment and outcome must be carefully considered. A more general “back-door criterion” provides sufficient conditions to determine whether all non-causal associations can be eliminated by adjusting for a (minimal) set of confounders L (Pearl, 2009, Chapter 3). The criterion consists of two parts. First, the variables in L block every back-door path between the treatment and the outcome (i.e., with an arrow pointing to treatment). Second, no variable in L is a causal descendant of treatment. Suppose L satisfies the back-door criterion with respect to a treatment Z and outcome Y . In that case, unconfoundedness of the causal effect of Z on Y given L holds regardless of the specific functional form or distribution of the variables (L, Z, Y) . Assessing whether the back-door criterion holds for a candidate adjustment set can be challenging, because a variable that is a non-collider on one path may be a (descendant of a) collider on another path. The R (R Core Team, 2021) package DAGitty (Textor et al., 2017) can aid visualizing causal diagrams, and automate determining whether a minimally sufficient subset of covariates exists to establish unconfoundedness. A minimal adjustment set is desirable because it reduces the number of variables for which functional dependencies with the treatment, outcome, or both treatment and outcome, must be specified when estimating the causal effect in the subsequent data analysis.

The back-door criterion provides a simple graphical criterion for determining whether unconfoundedness is possible when the structure of the causal diagram is known. But establishing a correct and realistic causal structure for all variables based solely on theoretical knowledge or prior empirical evidence can be difficult, if not impossible, in large observational studies. Under such settings, one possibility is to select covariates for confounding adjustment based on the observed data, provided that there exists a subset of (measured) covariates sufficient to establish unconfoundedness. However, valid inference following variable selection using the same data is no longer guaranteed when using routine variance estimators, with confidence intervals that are too narrow because the uncertainty introduced by the variable selection process is unaccounted for (Huang, 2020). Such data-adaptive covariate (or confounder) selection techniques for causal inference are beyond the scope of this article; see VanderWeele (2019) and Witte and Didelez (2019) for recent reviews. The plausibility of the unconfoundedness assumption that relies on a set of measured covariates should thus be scrutinized in each unique application toward a more resilient justification that the causal effect of interest can be unbiasedly estimated. Well-grounded justifications of the covariates either included in or omitted from adjustment should thus form part of the analysis (Foster, 2010; Austin and Stuart, 2015; Kainz et al., 2017).

Estimation of causal effects when unconfoundedness can be established

Now suppose that a (minimal) subset of covariates L has been determined, so that there are no variables - measured or unmeasured - that would undermine the unconfoundedness assumption. We may then proceed to estimate the ATE while adjusting for L . We describe a few approaches that build on prevalent regression models in the education research literature, but differ in terms of how the models are utilized to obtain an effect estimator.

Regression

A straightforward and common estimation approach is to simply regress the outcome Y on the treatment Z and the covariates L jointly in a multiple regression model. Traditional regression models are already widely used to describe the associations between independent and dependent variables, without necessarily alluding to causal relations. However, these techniques can also be employed as a parametric tool to adjust for confounding when assessing the causal effect of the treatment of interest on the outcome. When the causal effect is assumed to be homogenous and additive, the regression coefficient for the treatment is endowed with a causal interpretation, by essentially comparing the predicted outcomes between individuals with different treatment levels but having the same values of L . However, such an approach requires correctly specifying the associations between the covariates and the outcome in the assumed regression model.

Two possible issues arise when relying solely on routine outcome regression models for causal inference. First, the covariates may be moderators of the treatment-outcome relation, so that the treatment effect is modified by (possibly non-linear) combinations of the covariates. When the assumed model is overly parsimonious and includes only a single main effect for treatment, misspecification biases can arise because the heterogeneity of the treatment effect is implicitly averaged over the distribution of the covariates. A sufficiently flexible regression model with non-linear and higher order covariate-treatment interaction terms may be used to explicitly parameterize possibly heterogeneous treatment effects. However, conceptualizing such a model that

gives unbiased predictions - without impractically high variance of prediction - over the whole covariate space can be difficult or unfeasible in practice when there are many covariates, due to the curse of dimensionality. Second, biases due to extrapolation can arise when there is little overlap in the distributions of L between the treatment and control groups, particularly when L are strong predictors of Z , resulting in multicollinearity in the outcome model. The lack of empirical information about the treatment-outcome relation within disparate values of L that differ between the treated and untreated individuals requires extrapolating the covariate-specific outcome mean for the treated to the observed covariate levels for the untreated (and vice versa). Such extrapolation biases cannot be detected using routine checks of model assumptions, and can thus be difficult to diagnose and resolve (Vansteelandt and Daniel, 2014).

When the outcome of interest is collected in a nested or clustered setting, we can extend standard regression or single-level linear modeling approaches to multilevel models to account for the hierarchical structure of the data and dependency among units within clusters (Raudenbush and Bryk, 2002; Snijders and Bosker, 2011; Goldstein, 2011; Hox et al., 2017). Multilevel models, also referred to as hierarchical linear models or mixed-effects models, can incorporate different functional forms of covariates at different levels of the hierarchy, can attend to cross-level interactions, and allow for random (varying) coefficients of the intercepts and predictor effects across clusters. A treatment variable Z can be at a lower or upper level (e.g., treatment at the student level or school level), and the treatment effects at a lower level can be assumed to be constant across all units (i.e., fixed) or to vary across the clusters (i.e., random) in multilevel models. Strategies and techniques for causal inference specifically designed for such data structures will be described later in this section.

Matching

The aforementioned extrapolation biases can be avoided by eschewing a model-based approach for the associations between the outcome and covariates. Matching is a (non-)parametric method of adjustment for non-randomized treatment assignment that forms strata with exchangeable treated and untreated individuals (Rosenbaum, 2002). For example, suppose that the covariates L are low-dimensional and discrete, so that there are only a few unique values of L . Then individuals within non-overlapping strata defined by values of L are entirely indistinguishable from each other in all ways with respect to L , except for the observed treatment Z and (differences in) their potential outcomes. A straightforward comparison of observed outcomes between treated and untreated individuals within each stratum, followed by a weighted average of the (mean) differences with weights being the proportions of individuals in each stratum, would yield an unbiased estimator of the ATE. Matching therefore seeks to mimic a block-randomized design where each stratum corresponds to a block in which the distribution of L is identical among the treated and untreated individuals, and treatment is randomly assigned within each stratum.

However, full stratification on L to achieve unconfoundedness unavoidably results in fine-grained stratum-specific effects, even if interest is merely in the ATE. Furthermore, in most realistic settings, there are typically many variables in L , (some of) which may be continuous (i.e., taking on many possible values). Hence, unique strata defined using all possible combinations of values of L may not contain both treated and untreated individuals, even in very large sample sizes, due to the curse of dimensionality. This violates the aforementioned positivity assumption because individuals within a particular stratum have zero probabilities of being assigned to either treatment or control. While stratum-specific effects can be computed only for strata within which positivity and unconfoundedness hold, such strata may not be representative of the original population.

A commonly used alternative to a full stratification on the covariates is to model instead the associations between the treatment and covariates. The *propensity score* is the conditional probability that an individual would have been assigned treatment given their covariates (Rosenbaum and Rubin, 1983b), and is widely used in educational and psychological research (McCaffrey et al., 2004; Cook et al., 2009; Harder et al., 2010; Shadish and Steiner, 2010; Austin, 2011; Thoemmes and Kim, 2011; Lanza et al., 2013; West et al., 2014; Keller and Tipton, 2016; Dong et al., 2020; Powell et al., 2020). A key property of the propensity score is that the covariate distributions are rendered (approximately) similar, or “balanced,” across the treated and untreated groups by conditioning on the propensity score, provided unconfoundedness is met, and the model for the treatment given the covariates is correctly specified.

When the covariates in L are sufficient to eliminate all confounding of the treatment-outcome relation, then adjustment for the propensity score is also sufficient to achieve unconfoundedness. In other words, the potential outcomes and treatment are conditionally independent among individuals with the same propensity score, so that treated and untreated individuals with the same propensity score are exchangeable. The propensity score can then be viewed as a single stratifying variable to construct matched sets of treated and untreated individuals with identical propensity score values. The outcomes between treated and untreated individuals within each stratum - defined by a matched set - can then be contrasted. The average treatment effect is the weighted average of the average stratified treatment effect estimates. Because the propensity score is scalar, it permits using simple and transparent methods for confounding adjustment that would otherwise be impossible in the presence of high-dimensional covariates. Note that estimated propensity scores do a better job of balancing the observed covariates than the true propensity scores would, because the estimated propensity scores correct for the chance imbalances that characterize any finite sample (Rosenbaum, 1987a).

However, in finite samples, it may be unfeasible for different individuals (with different treatment levels) to have exactly the same estimated propensity score. Individuals with similar but unequal propensity scores must therefore be matched to the same stratum using a pre-determined similarity criterion. For example, subclassification (or interval matching) partitions individuals into equally-sized subgroups based on the sample quintiles of the propensity score distribution (Cochran, 1968). But there is

no guarantee that each subgroup will contain both treated and untreated individuals so that the positivity assumption is upheld. A data-adaptive alternative is full matching (Hansen, 2004), which creates partitions that minimize the within-subgroup average difference in the estimated propensity score (and thus the distribution of the covariates), while ensuring that at least one treated and one untreated individual is in each subgroup. Other matching algorithms seek to optimize the within-sample balance of the (observed joint distribution of the) covariates for the treated and untreated individuals within each subgroup (Diamond and Sekhon, 2013). Various R packages implementing different matching algorithms include *cem* (Iacus et al., 2009), *Matching* (Sekhon, 2011), and *MatchIt* (Ho et al., 2011). Stuart (2010) provides a review of matching algorithms.

An alternative to constructing matched sets using the estimated propensity scores is to directly employ the propensity scores as inverse weights when comparing the outcomes between treated and control individuals (Lunceford and Davidian, 2004). Let $p(L_i)$ be the propensity score for individual i whose covariate values are L_i . Define the inverse probability (of treatment) weights as:

$$W_i = \frac{Z_i}{p(L_i)} + \frac{1 - Z_i}{1 - p(L_i)} \quad (1)$$

Each individual is weighted by the inverse of their probability to receive their observed treatment given the observed covariates, thus creating a pseudo-population where Z is no longer associated with L and there is no confounding bias when comparing treated and untreated individuals in such a pseudo-population. Both the treatment and control groups then have the same weighted distribution on (observed) common causes of treatment and outcome as the pseudo-population. Estimation predominantly proceeds by first fitting a logistic regression model for the treatment given the covariates, commonly referred to as the *propensity score model*, to the observed data, such that covariate balance is achieved. The fitted propensity score for each individual is obtained by plugging in the maximum likelihood estimates of the model parameters for their unknown values. Let $\widehat{W}_i$ denote the estimated weight from plugging in $\widehat{p}(L_i)$ for $p(L_i)$ in (1). An estimator of the ATE is then the treatment coefficient in a weighted linear regression of the outcome versus treatment (only) using $\widehat{W}_i$ as the individual weights. An asymptotic Wald $100(1 - \alpha)\%$ confidence interval (CI) can be calculated using the robust (sandwich) variance estimator, and the critical values from a standard Normal distribution (Austin and Stuart, 2017). Note that no model for the outcome, conditional on treatment and the covariates, is required to be (correctly) specified for unbiased estimation of the ATE. A benefit of weighting individuals by their inverse propensity score is that known survey weights - constructed to account for complex observational study design features - can be readily accommodated by simply multiplying each individual's survey weight by W_i .

A shortcoming of inverse propensity score weighting is its reliance on the estimated propensity scores. Estimated values close to zero or one can lead to disproportionately large weights that give undue influence to a small subset of individuals relative to the remainder of the sample. In particular, the resulting skewness and sampling variability in the tails of the propensity score distribution occasionally result in erratic estimates relative to traditional outcome regression adjustment. Nonetheless, the larger standard errors more honestly reflect the uncertainty about the causal effect because no empirical information (or assumptions) about the joint distributions of covariates and potential outcomes are explicitly used (Tan, 2006). One solution in practice is to trim back the weights (Petersen et al., 2012), by progressively truncating extreme values to interior percentiles of the initial estimated distribution (i.e., first back to the 1st and 99th percentiles, then the 2.5th and 97.5th percentiles, and so on.) However, this may render bias in the effect estimate. A recommended solution is to consider alternatives to standard logistic regression for the propensity score. For example, *covariate balancing propensity scores* (Chattopadhyay et al., 2020; Imai and Ratkovic, 2014) directly maximize balance of the (observed) covariate distributions across the treated and untreated groups when estimating the optimal model parameter values that determine the weights. Alternatively, propensity scores may be estimated using computationally intensive but flexible machine learning techniques (Lee et al., 2010), such as generalized boosted models (McCaffrey et al., 2004; Setodji et al., 2017), with an R implementation in the *twang* package (Cefalu et al., 2021); classification trees (Luellen et al., 2005); or neural networks (King and Zeng, 2001; Setoguchi et al., 2008). Webster-Clark et al. (2021) provide a recent review of propensity score methods, while Kainz et al. (2017) offer practical recommendations for using propensity scores.

In the presence of multilevel data, propensity scores that account for the nested or clustered structure while directly optimizing covariate balance between the treatment groups can be employed (Kim et al., 2017; Yang, 2018; Fuentes et al., 2021). Because clusters constitute natural strata, matching can be conducted within clusters if sample sizes are not too small and the numbers of both treated and untreated cases are sufficient in all clusters (Kim and Seltzer, 2007). In many empirical studies, however, sample sizes may be too small or the positivity assumption will be violated in some or many clusters, and thus within-cluster matching is not feasible. In such circumstances, across-cluster matching techniques can effectively "borrow units" from other clusters to improve overlap between treated and untreated cases (Thoemmes and West, 2011; Steiner et al., 2012). Combinations of within- and across-cluster matching have also been proposed (Arpino and Cannas, 2016; Zubizarreta and Keele, 2017). As a matching strategy for multilevel data, Kim and Steiner (2015) applied latent class selection models for evaluating heterogeneity in the selection processes and classifying clusters into a small number of homogeneous groups (i.e., latent classes), and then pooling cases within latent class. This "across-cluster within-classes" matching method can be used when the class memberships are known (manifest classes) or unknown (latent classes). Similarly, Kim et al. (2016) used finite mixture models for estimating heterogeneous treatment effects where private tutoring was effective for a small class of students but not for the rest. The across-cluster within-class matching also weakens an important assumption for causal models in that the unconfoundedness assumption is required within each class but not across the classes. There has also been increasing use of machine learning methods for causal inference with observational multilevel data (Suk et al., 2020, 2021). In summary, a variety of procedures are possible for matching in the presence of multilevel data structures.

Estimators that combine propensity scores and outcome regression models

Without a perfect specification of the propensity score model, one cannot be assured that consistent estimates can be obtained. Because propensity scores are intended to eliminate the treatment-confounder associations by weighting the observed sample so that it is representative of a pseudo-population, systematically incorrect estimated propensity scores can generate systematically incorrect weighting schemes that yield inconsistent estimates of treatment effects.

We now discuss three possible estimation methods that combine the use of propensity scores and outcome regression models. Such “doubly-robust” estimators are appealing because they offer protection against model misspecification biases when either model is correctly specified (Robins, 2000; Bang and Robins, 2005). The estimators differ in terms of how the estimated propensity scores are utilized in the outcome regression model. A straightforward approach is to include the propensity score as an additional predictor in an outcome model, referred to as “regression adjustment for the propensity score” (D’Agostino, 1998). Suppose that the outcome is continuous, and regressed against treatment, covariates, and the propensity score in a linear model. Provided that the relation between the outcome and the true (but unknown) propensity scores is correctly specified, the ordinary least squares estimator of the treatment coefficient, with the estimated propensity scores used in place of their true values, is an unbiased estimator of the ATE in large samples when the propensity score model is correctly specified and the exposure effect is homogenous. Under these conditions, the ordinary least squares estimator of the ATE does not necessitate correct specification of the outcome regression model and is thus not vulnerable to extrapolation biases under that model. Because the propensity scores are a summary of the covariates that suffices to ensure ignorability, the propensity scores completely remove the bias in estimating the ATE and any additional information provided by them merely serves to make the estimate more precise (Vansteelandt and Daniel, 2014).

Conversely, suppose that the outcome model is correctly specified before the propensity scores are added, in the sense that the outcome model given treatment and covariates (i.e., without the propensity scores) are unbiased for the true data-generating mechanism of the potential outcomes. Adding (any function of) the propensity scores merely results in an overfitted outcome model, and adds mean-zero noise to the predicted outcomes, so that the choice of propensity score model does not affect the validity of the estimator. Hence the ATE estimator is unbiased even if the propensity score model is misspecified (Vansteelandt and Daniel, 2014). In other words, an unbiased estimator of the ATE can be obtained so long as either the outcome model or the propensity score model is correctly specified. In general, functions of the estimated propensity scores can be incorporated into the outcome model as additional predictors. For example, smoothing splines with knots at the sample quintiles of the logit of the propensity score (i.e., linear predictor in the propensity score model) (Little and An, 2004), or indicators of strata membership following subclassification on the propensity score using the sample quintiles (Kang and Schafer, 2007), can be used.

However, when a nonlinear model for the outcome is employed, such as with a canonical link function in a generalized linear model, the benefits of adjusting for the (estimated) propensity score in the outcome model are more subtle. The protection offered against model misspecification is then limited to only tests of the null hypothesis of no treatment effect that are based on a robust variance estimator. Under such settings, the hypothesis tests have the correct type I error rate (in large samples) when either the propensity score model, or the outcome regression model, is correctly specified (Vansteelandt and Daniel, 2014).

An alternative estimator can be obtained by weighting the observations in the outcome regression model (given treatment and covariates) using the weights W_i as defined in (1). Estimation proceeds by first estimating W_i , then fitting the outcome regression model with each observation weighted using the estimates of W_i . The estimator of the ATE is then the weighted least squares estimator of the treatment coefficient, and is consistent so long as either the outcome model or the propensity score model is correctly specified (Robins et al., 2000).

The approaches so far encode the ATE as the treatment coefficient in a parametric model for the outcome. A third approach avoids such an explicit parametrization by augmenting the inverse probability (of treatment) weights estimator with an outcome model to exploit information about the treatment effects. The potential outcomes can then be imputed, and an estimator of the ATE calculated without necessarily being encoded as a parameter in the outcome model. An example of a so-called *augmented inverse propensity weighted* (AIPW) estimator (Robins et al., 1994) can be defined as follows. Let $\widehat{W}_i$ denote the estimated weights, as defined in (1), for individual i . Let $\widehat{E}(Y_i|Z_i, L_i)$ denote the outcome regression model fitted to the observed data that we will use to predict the (potential) outcomes for each individual under different (hypothetical) treatments. The estimator of the ATE given a sample of size n is then:

$$\begin{aligned} \frac{1}{n} \sum_{i=1}^n Z_i \widehat{W}_i \{Y_i - \widehat{E}(Y_i|Z_i = 1, L_i)\} - (1 - Z_i) \widehat{W}_i \{Y_i - \widehat{E}(Y_i|Z_i = 0, L_i)\} \\ + \{\widehat{E}(Y_i|Z_i = 1, L_i) - \widehat{E}(Y_i|Z_i = 0, L_i)\}. \end{aligned} \quad (2)$$

Such AIPW estimators have a number of appealing properties (Glynn and Quinn, 2010). In particular, they are consistent if either the propensity score model or outcome model is correctly specified, and asymptotically unbiased when both are correctly specified. Hence, they permit reducing the reliance on traditional parametric regression models that demand (correctly) specifying the exact relationships between the covariates and treatment, or outcome, or both. These relationships may be complex and inadequately understood using existing theory, resulting in biases due to inaccurate predictions of the propensity scores, or outcomes, or both. To mitigate the risks of biases due to misspecified models, richly parameterized models with multiple higher-order interaction terms and flexible functional forms (e.g., cubic or smoothing splines) for the predictors in L can be fitted instead. However, it may be difficult or unfeasible to fit such models in practice, because the number of parameters will be very large relative to the sample size.

Such constraints may be overcome by considering (*supervised*) machine, or statistical, learning algorithms designed to accurately predict dependent variables given a set of independent variables (or features). For example, nonparametric regression methods (such as generalized additive models; [Hastie et al., 2009](#)), or tree-based algorithms (such as random forests; [Breiman, 2001](#)) and Bayesian additive regression trees (BARTs; [Chipman et al., 2010](#)), can be used to estimate the conditional expectations of the potential outcomes, while permitting flexible and arbitrarily complex functional forms of L . Because these algorithms can be trained to optimize predictive accuracy while incorporating a large number of parameters, they can outperform traditional parametric models for the accurate prediction of conditional expectations. For example, AIPW estimators using machine learning techniques are implemented in the R package AIPW ([Zhong et al., 2021](#)). But caution needs to be exercised to avoid overfitting that can render invalid inferences when using predictive machine learning algorithms ([Vansteelandt, 2021](#)). In the concluding section, we provide recent examples of machine learning-based causal inference methods for estimating heterogeneous causal effects.

Sensitivity analysis to unmeasured confounding

Applied researchers intending to conduct causal inference in an observational study should seek to measure and adjust for all relevant confounders toward eliminating biases due to unmeasured confounding. But in most realistic settings, confounders likely remain unadjusted for, raising the prospect of invalid inferences. A common setting is when there are confounders for which it is unfeasible or impractical to observe or collect data. Therefore, it is judicious to conduct a sensitivity analysis addressing unmeasured confounding by judging the (minimum) extent to which substantive conclusions would differ after adjusting for an additional hypothetical unmeasured confounder.

A widely-adopted approach focuses on characterizing the (strength and direction of) association between the hypothetical confounder and the treatment as a sensitivity parameter ([Rosenbaum, 1987b](#)). However, a large confounding bias requires a strong confounder-treatment association and a strong confounder-outcome association (conditional on the treatment). Hence another approach further incorporates the (strength and direction of) association between the hypothetical confounder and the outcome as an additional sensitivity parameter ([Rosenbaum and Rubin, 1983a](#); [Lin et al., 1998](#); [Imbens, 2003](#)). The sensitivity analysis proceeds by (i) specifying different values for the sensitivity parameters, (ii) repeating estimation of the causal effect while adjusting for the hypothetical confounder under each fixed value of the sensitivity parameters in turn, and then (iii) assessing the relative sensitivity of the results across the range of values. Graphical tools, such as bivariate sensitivity contour plots that visualize different combinations of how strongly the hypothetical confounder must be (simultaneously) associated with the exposure and outcome for the conclusions to be affected, can be especially useful ([Carnegie et al., 2016](#); [Ding and VanderWeele, 2016](#); [Dorie et al., 2016](#); [VanderWeele and Ding, 2017](#)). Such methods require users to calibrate the range and granularity of the values of the sensitivity parameters. Alternatively, Bayesian sensitivity analyses for unmeasured confounding ([Greenland, 2003a](#); [McCandless and Gustafson, 2017](#)) avoid such user calibration through the application of Bayes Theorem to obtain a posterior distribution for the sensitivity parameters in the outcome model. We refer readers to [Liu et al. \(2013\)](#) for an overview of other approaches.

Estimating causal effects when unconfoundedness is precluded

It may be unfeasible to record all relevant confounders in practice, thus precluding unconfoundedness from being reasonably assumed to hold. Under such settings, confounding cannot be removed, even with an infinite sample size, and the ATE is non-parametrically (point) unidentifiable. Quasi-experimental designs and natural experiments, such as *regression discontinuity* ([Thistlethwaite and Campbell, 1960](#)), *difference-in-differences* ([Card and Krueger, 1994](#)), and instrumental variable analysis ([Angrist et al., 1996](#)), permit alternative causal inference approaches that can reduce the reliance on the unconfoundedness assumption ([Cook et al., 2002](#); [Angrist and Pischke, 2008](#); [Kim and Steiner, 2016](#)).

However, the validity of these approaches are contingent on their own set of causal assumptions. We briefly describe the assumptions for the instrumental variable approach. Consider the setting depicted in the causal diagram of [Fig. 1i](#) where the causal effect cannot be identified due to unmeasured confounding by U_{ZY} . An instrumental variable such as A can permit causal inference about the effect of Z on Y . A specific setting in the context of randomized experiments is when partial (or non-) compliance arises, so that certain individuals are less likely than others to adhere to the (randomized) treatment. The randomized treatment then plays the role of an instrumental variable for the treatment experienced by (or provided to) each individual; see e.g., [Swanson et al. \(2018\)](#). However, the validity of the instrumental variables approach demands three core assumptions about the causal structure ([Glymour et al., 2012](#)): (i) there is no unmeasured confounding of the instrument and the outcome of interest, (ii) the instrument must be associated with the treatment of interest, and (iii) every directed path from the instrument to the outcome must pass through the treatment (commonly termed “exclusion restriction”). Assumption (i) is depicted by the absence of back-door paths between A and Y ; assumption (ii) is depicted by the arrow from A to Z ; and assumption (iii) is depicted by the absence of a directed path from A to Y . Identification of the causal effect demands a further so-called “monotonicity” assumption that the conditional expectation of (counterfactual) treatment given the instrument satisfies certain distributional constraints. Efforts have thus focused on evaluating these assumptions; see e.g., [Swanson and Hernán \(2013\)](#), [Yang et al. \(2014\)](#), [Pizer \(2016\)](#), [Labrecque and Swanson \(2018\)](#), and [Lousdal \(2018\)](#). We refer readers to [Goetghebeur et al. \(2020\)](#) for an accessible introduction to instrumental variable based methods.

Summary and recent advances

Studying cause-effect relationships to elevate understanding of the behavioral, social, or other mechanisms leading to an outcome is central in education research and practice. While well-designed randomized experiments may be the gold standard for causal inference, they are often unfeasible in practice due to ethical concerns or logistic challenges. In observational studies where participants can select their treatment, spurious correlations between the treatment and the outcome - arising from their mutual association with a confounder that is unadjusted for - can lead to misleading causal conclusions.

We presented the potential outcomes framework for formalizing the causal impacts of interventions, or treatments, on outcomes. We have stated the key assumptions for identifying and estimating average treatment effects, namely the stable unit treatment value assumption (SUTVA), unconfoundedness, and positivity. We have introduced causal diagrams for representing causal relations between variables that are grounded in theory. In particular, causal diagrams are an essential tool to determine which covariates should and should not be adjusted for when seeking to identify the causal effect. We provided examples of simple causal diagrams explaining why certain covariates should or should not be adjusted for. We have reviewed widely used analytic techniques for estimating the treatment effects, such as covariate adjustment, propensity scores, and other matching techniques, as well as combinations of treatment selection and outcome models. However, these estimation methods are contingent on assuming that unconfoundedness can be met, which is not always plausible. Therefore, we have additionally described sensitivity analyses for unmeasured confounding. Natural experiments such as instrumental variable based methods are attractive alternatives for causal inference when unconfoundedness cannot be reasonably assumed to hold. However, they require their own set of causal assumptions for valid inference. Due to the prevalence of multilevel data structures in education, we also presented strategies and statistical tools for conducting causal inference with observational multilevel data.

We state a few recent advances in causal models that may drive education research in exciting directions. Scientific interest often lies in disentangling causal effects transmitted through intermediate variables on the causal path between treatment and outcome, such as M in the causal diagram of Fig. 1d. Using potential outcomes to conceptualize (in)direct effects can be especially fruitful under the *causal mediation analysis* framework. Model-free definitions of *natural direct and indirect effects*, first developed by Robins and Greenland (1992) and Pearl (2001), do not rely on any assumed statistical models, and therefore enable extensions to non-additive and non-linear models (MacKinnon et al., 2020). Furthermore, the framework facilitates formalizing the unconfoundedness (or “sequential ignorability”) assumptions necessary for decomposing the total effect into a direct and an indirect effect (Imai et al., 2010; Pearl, 2014). When there are multiple simultaneous mediators, valid causal inferences about the indirect effects via each mediator can be obtained, even without assuming a causal structure among the mediators, or when the mediators share unmeasured confounders (Loh et al., 2021). We refer readers to Nguyen et al. (2021) for an introduction, and VanderWeele (2015) for a book-length exposition.

Multilevel data structures are common in educational settings where repeated measures, individuals, and educational clusters correspond to different levels (Raudenbush and Bryk, 2002; Snijders and Bosker, 2011; Goldstein, 2011; Hox et al., 2017). Under such nested or clustered data structures, omitted variable bias in estimation is likely to arise due to unmeasured confounding at upper (such as classroom or school) levels (Kim and Frees, 2006; Kim, 2009; Arpino and Mealli, 2011; Li et al., 2013; Fuentes et al., 2021). Because random effects estimation approaches are inadequate to adjust for such unmeasured upper-level confounding, fixed effects estimation approaches are recommended to eliminate such bias (Hazlett and Wainstein, 2020; Imai and Kim, 2020; Kim and Steiner, 2021). However, they may be unreliable, e.g., when cluster sizes are small or some clusters contain few or no (un)treated observations; or undesirable, e.g., when the effects of school, teacher, or student characteristics on the outcome are of interest. Kim and Frees (2007) introduced the generalized method of moments (GMM) estimator as an alternative estimator when the random effects estimator is biased and the fixed effects estimator is impractical. Omitted variable tests for multilevel data and robust GMM estimation are implemented in the R package REndo (Gui et al., 2021) that fits linear models with endogenous regressors.

A component of SUTVA restricts an individual’s potential outcomes to depend only on their experienced treatment. This may be overly restrictive in settings where individuals are causally connected (Raudenbush and Schwartz, 2020). Continuing the example in the introduction, if the impact of private schooling on the academic outcomes of Alex depended on whether their next-door neighbor and closest friend Cameron went to the same school, then this would violate SUTVA. More general definitions of the potential outcomes under (treatment) interference (Cox, 1958) permit assessing peer (influence), or spillover, effects when evaluating the impacts of educational interventions. Analytic strategies and techniques that build on the potential outcomes framework include Sobel (2006), Hong and Raudenbush (2006), Aronow et al. (2021), and Loh and Ren (2020) among many others; see Halloran and Hudgens (2016) for a comprehensive review.

We have focused on the average treatment effect in an entire population of interest. But variation of the effect across different groups of individuals is often expected because individuals vary in their susceptibilities to treatment. Hence interest is often in discerning effect heterogeneity to inform future interventions targeted at specific subgroups (Mayer et al., 2019). Effect heterogeneity across strata of a given pre-treatment modifier V can be assessed by simply computing the average treatment effect of Z on Y within each level of V . Researchers should thus collect data on pre-treatment covariates, even in randomized experiments, to investigate effect heterogeneity. In an observational study, V may be a subset of the confounders L needed for unconfoundedness to hold. The remaining variables in L must then be adjusted for (within each stratum of V) following the above procedures. When either the variables V that induce treatment effect heterogeneity, or the functional forms reflecting how V modify the treatment

effect, are unknown, machine learning algorithms can be exploited to adaptively uncover V from among a large set of variables in L , while permitting flexible functional forms of L (including V) to estimate the conditional ATE (CATE). Recent developments such as *causal forests* (Athey and Wager, 2019), *Bayesian causal forests* (Hahn et al., 2020), *targeted minimum loss estimation* (TMLE) (Van der Laan and Rose, 2011), and *metalearners* (Künzel et al., 2019), employ different machine learning algorithms to estimate the propensity score model, or the outcome model, or both. Comparisons of these cutting edge methods have been made in causal inference data analysis competitions (Carvalho et al., 2019; Dorie et al., 2019).

Acknowledgments

The authors thank Peter Steiner, Dan Bolt, Louise Poppe, and Caroline Keck for their detailed and insightful comments on an earlier version of this manuscript.

Glossary

Artificial Intelligence (AI) the simulation of human intelligence processes by machines, especially computer systems. Specific applications include expert systems, natural language processing, speech recognition and machine vision

Artificial Neural Network a collection of connected units called artificial neurons, which loosely models a biological brain and used to learn data representations

Convolutional Neural Network a class of artificial neural network, most commonly applied to analyze visual imagery and contains convolutional layers

Deep Learning a family of machine learning methods based on artificial neural networks that contain many hidden layers

Machine Learning the use and development of computer systems that learn from examples and automatically draw inferences and detect patterns in data

Recurrent Neural Network a class of artificial neural networks where connections between nodes form a directed graph along a temporal sequence, used for language translation, natural language processing and speech recognition

Stochastic Gradient Descent (SGD) an iterative algorithm for optimizing an objective function, used for training neural networks

Supervised Learning the machine learning task of learning to predict the label of an input example

Transfer Learning a machine learning method where a model developed for a task is reused as the starting point for a model on a second task

Reinforcement Learning the machine learning task of operating in an environment using feedback, without a fixed training data set.

Unsupervised Learning the machine learning task of learning patterns and relationships in data from unlabeled examples

Introduction

Machine learning (ML) is the use and development of computer systems that can *learn through experience*, i.e., gradually improve their performance on a task, by using algorithms and statistical models that draw inferences and detect patterns in data (Wikipedia, 2021a,b,c). This is accomplished by automatically adapting data structures and parameters to optimize an objective function, as

more data are shown to the system. ML is considered a subset of Artificial Intelligence (AI), and has become the dominant data-driven approach in a great number of fields where an enormous amount of data are available, but it is difficult or unfeasible to develop conventional algorithms to perform the task. These include image recognition for medical diagnosis (Varela-Santos and Melin, 2021), speech recognition (Hussain et al., 2022), automatic language translation (Lakew et al., 2018), stock market trading (Sonare et al., 2021), and online fraud detection and e-mail spam filtering (Fu et al., 2016). From “Google Search by Voice” to self-driving cars, ML is all around us nowadays.

Educational measurement is undergoing a similar transformation. Digitally Based Assessments (DBAs) enable the capture of a broad range of test takers’ response process information at finer time granularity than traditional psychometrics, in areas of problem solving (Hao et al., 2017; Polyak et al., 2017), communication and collaboration (von Davier et al., 2017), via chats and games (Wu et al., 2016; Kim and Shute, 2015). These rich process data can provide new opportunities for validating assessments, improving measurement precision, examining response patterns, and identifying new constructs (Neiriz et al., 2017; Mislevy et al., 2014). But these potential benefits do not come for free. The significantly increased volume, velocity, and variety of data pose new challenges to psychometricians for handling, analyzing, and interpreting the data to materialize their value. ML is a critical component of the analysis, combined with natural language processing (Clark et al., 2010), educational data mining, and computer vision (Huang and Khan, 2021).

Types of machine learning

Supervised learning

Supervised learning describes a class of problem that involves using a model to learn a mapping between input examples and a target variable (Brownlee, 2019). Supervised learning problems are either classification problems (predicting a categorical class label) or regression problems (predicting a numerical label). For instance, the input example could be a student’s essay (say, encoded into a vector of words), and the label would be a human-graded score (either categorical or continuous).

In a typical pipeline (cf. Fig. 1), input examples are annotated and divided into a training, validation, and test sets (also called “folds”; a typical splitting is 70%-15%-15%). The machine learning model of choice, e.g., decision trees (Topirceanu and Grossecck, 2017) or Support Vector Machines (SVM) (Cristianini and Ricci, 2008) is first trained on the training set, and its prediction accuracy is evaluated on the validation set. This is repeated for multiple values of global model hyper-parameters (e.g., the soft margin value γ in SVM, which controls the margin between different classes and the number of allowed classification mistakes), and the optimal hyper-parameters values that approximately maximize validation accuracy are chosen. Finally, the test set accuracy is measured and reported. The test set must not be used during the training process, otherwise the prediction accuracy may be inflated due to overfitting.

Unsupervised learning

Unsupervised learning refers to a class of problems that involves using a model to describe or extract relationships in data. As opposed to supervised learning, the input data is unlabeled. This does not require data annotation, which is typically a tedious and costly task (e.g., scoring thousands of essays by hand); on the other hand, unsupervised learning does not have a teacher correcting the model (Goodfellow et al., 2016).

The most common unsupervised learning task is **clustering**: finding groups in data. For instance, an automated essay evaluation system might gradually develop a concept of “good essays” and “bad essays” without ever being given scored essays. Examples of clustering algorithms are k-Means, mean-shift clustering, Density-Based Spatial Clustering of Applications with Noise (DBSCAN), expectation-maximization clustering using Gaussian mixture models, and agglomerative hierarchical clustering (Seif, 2018). Clustering quality is measured by the *silhouette score*, a measure of how similar an object is to its own cluster (cohesion) compared to other clusters (separation) (Rousseeuw, 1987). If the data is high-dimensional, it is typically first *projected* into a lower-dimensional space representation before clustering (Fig. 2).

Another unsupervised learning task is *density estimation*: summarizing the distribution of data. A popular solution method is kernel density estimation (Gramacki, 2017).

Fig. 1 Supervised machine learning model life cycle. Adapted from Miao et al. (2017).

Fig. 2 The MNIST database (Wikipedia, 2021a,b,c) is a large database of handwritten digits used as a common machine learning benchmark. (A) Supervised learning. Each input example is a 28×28 pixel black-and-white image labeled as 0, 1, ..., or 9. Both the images and labels are used during training. New unlabeled images can then be fed into the trained model for prediction. (B) Unsupervised learning example of projecting MNIST images into a two-dimensional plane and clustering them into 10 groups. (A) Reproduced from Wikipedia (2021a,b,c); (B) Reproduced from Silbernagel (2019).

Other types of learning

Reinforcement learning describes a class of problems where an agent operates in an environment and must learn to operate using feedback (Sutton and Barto, 2018). For instance, a collaborative learning system may include a “bot” that can interact with learners (offering hints or assisting in problem solving) based on their inputs. Here there is no fixed training data set, rather “a goal or set of goals that an agent is required to achieve, actions they may perform, and feedback about performance toward the goal” (Brownlee, 2019).

Other types of learning include *semi-supervised learning* (supervised learning where the training data contains very few labeled examples and a large number of unlabeled examples), *multi-instance learning* (individual examples are unlabeled, but groups of examples are), and *self-supervised learning* (unsupervised learning problem framed as a supervised learning problem for which supervised learning algorithms can be applied) (Brownlee, 2019).

Deep learning

Deep learning is a family of machine learning methods for extracting patterns from data using *Artificial Neural Networks (ANNs)*. Deep learning can be supervised, semi-supervised or unsupervised. DNN frameworks can model complex non-linear relationships. Early ANNs date to the 1960s (Rosenblatt, 1962), but their application was limited by data availability and computing power. Renewed interest started in the late 1990s when DNNs were applied to reading over 10% of all the checks in the United States (LeCun et al., 2010). Following breakthrough work (Krizhevsky et al., 2012) in 2012, where DNNs trained on massively labeled data using Graphical Processing Units (GPUs) halved the error rate of state-of-the-art computer vision systems on the ImageNet object recognition challenge, deep learning has emerged as a hot research field, with thousands of publications every year, and prestigious conferences including the Conference on Computer Vision and Pattern Recognition and International Conference on Computer Vision.

DNNs have been successful in many fields, outperforming traditional ML methodologies and sometimes surpassing human expert performance. Application areas include non-linear system control (robotics, self-driving car, process control) (Grigorescu et al., 2020), game-playing and decision making (backgammon, chess, racing, and Go (Silver et al., 2016); cf. Fig. 3), pattern recognition (radar systems, face identification, object, speech and hand-writing recognition) (LeCun et al., 2010), natural language processing (language translation, language generation, and time-series analysis) (Devlin et al., 2019), medical diagnosis (Amato et al., 2013), financial applications (check recognition, fraud detection) (Fu et al., 2016), visualization, Email spam filtering (Dada et al., 2019).

DNNs are attractive because they perform well without external human-designed structures or time-intensive feature engineering. Despite their advantage, their use in educational applications has been limited (Huang and Khan, 2021). Section **Applications to educational measurement** showcases illustrative examples of many recent papers, and there is much room for the development of deep neural networks for educational data classification with complex standards and taxonomies, time-series modeling, recommendation systems that identify learners’ individual styles, and new content generation.

The artificial neuron

A biological neurons receives real-valued input $\mathbf{x} = (x_1, \dots, x_m)$ from other neurons (hundreds in small organisms to 10^4 – 10^5 in the human brain (Herculano-Houzel, 2009)) via synapses (Fig. 4A). Inputs are approximately summed, and if the value exceeds

Fig. 3 AlphaGo versus Lee Sedol, also known as the Google DeepMind Challenge Match, was a five-game Go match between 18-time world champion Lee Sedol and AlphaGo, a deep-learning Go program developed by Google DeepMind, played in Seoul, South Korea between 9 and March 15, 2016. AlphaGo won 4-1. The match has been compared with the historic chess match between Deep Blue and Garry Kasparov in 1997, where computers surpassed the best humans in the world in an advanced cognitive skill. Reproduced from [Armasu \(2016\)](#).

Fig. 4 (A) A biological neuron connected to input neurons. (B) The artificial neuron (perceptron), a nonlinear gate mapping $m = 4$ inputs to an output. (A) Reproduced from [Shen \(2013\)](#).

a threshold the neuron sends an electrical spike to the next neurons. All neurons send signals simultaneously, enabling massively parallel processing.

The basic building block of an artificial neural network is a *perceptron* ([Rosenblatt, 1958](#)). It is a binary classifier, i.e., a function f that maps a real-valued input vector $\mathbf{x} = (x_1, \dots, x_m)$ to a scalar binary output value:

$$f(\mathbf{x}; \boldsymbol{\theta}) := \begin{cases} 1, & \text{if } \mathbf{w} \cdot \mathbf{x} + b > 0, \\ 0, & \text{otherwise,} \end{cases} \quad (1)$$

where $\mathbf{w} \cdot \mathbf{x} = \sum_{i=1}^m w_i x_i$, and $\boldsymbol{\theta} = (\mathbf{w}, b)$ are *learned parameters* ([Fig. 4B](#)).

Basic fully-connected architecture

The goal of a neural network is to approximate a function f^* , for instance, $y = f^*(x)$ mapping the input x to the class y . The network defines a mapping $f(\mathbf{x}; \boldsymbol{\theta})$ and learns the value of the parameter vector $\boldsymbol{\theta}$ that results in the best function approximation. In a *feed-forward* network data flows from the input layer to the output layer without looping back. A network with feedback connection is called a *recurrent neural network* (cf. [Sec. Recurrent neural networks](#)) [19, Chap. 6].

An l -layer neural network (also known as a “multi-layer perceptron network” ([Rosenblatt, 1958](#))) is a mapping f of an input vector $\mathbf{x}$ to an output $y = f(\mathbf{x})$ (typically a scalar), comprising of layers $\mathbf{x}^{(1)}, \mathbf{x}^{(2)}, \dots, \mathbf{x}^{(l)}$, where the first layer is the input $\mathbf{x}^{(1)} = \mathbf{x}$, followed by $l - 2$ hidden layers, and the output layer $\mathbf{x}^{(l)} = y$. Each layer is a vector of *neurons*, also called *units*. A neuron is a perceptron whose hard-thresholding is replaced by a differentiable *non-linear activation function* σ (such as tanh, sigmoid or rectified linear).

In a *feed-forward* network data flows from the input layer to the output layer without looping back. Each neuron is connected to some of the previous layer’s neurons. In this section we are discussing a *fully-connected* layer, in which it is connected to *all* of them

Fig. 5 (A) A four-layer fully-connected neural network. Each link contains a learned parameter, e.g., $w_{4,3}^{(2)}$ connects $x_3^{(2)}$ to $x_4^{(3)}$. Each neuron (except the input layer) has a learned bias parameter. (B) Comparison of training algorithms (optimizers) for the MNIST hand-written digit recognition task. Reproduced from Diederik (2017).

(as opposed to convolutional layers, for instance, which are sparse; cf. Sec. **Convolutional Neural Networks**). Layer $k + 1$ is calculated from layer k by

$$x^{(k+1)} = \sigma(W^{(k)}x^{(k)} + b^{(k)}), \quad (2)$$

where $W^{(k)}$ is a weight matrix, $b^{(k)}$ is a bias vector, and σ is applied element-wise. The last layer may employ a different function g to combine $x^{(L-1)}$ into the final output (e.g., softmax (Wikipedia, 2021a,b,c)). For instance, a four-layer network (Fig. 5A) defines the mapping

$$y = f(x; \theta) = g(W^{(3)}\sigma(W^{(2)}\sigma(W^{(1)}x + b^{(1)}) + b^{(2)}) + b^{(3)}), \quad (3)$$

where θ denotes the vector of learned parameters, consisting of all the elements of $W^{(1)}, b^{(1)}, \dots, W^{(L-1)}, b^{(L-1)}$.

Model training

During training, the parameters θ are *learned* by minimizing a *loss function* $J(\theta)$, which is a performance measure (e.g., prediction accuracy) evaluated over the entire training set. For instance, an L_2 loss is often used for a regression problem:

$$J(\theta) = \sum_i \|y_i - f(x_i; \theta)\|_2^2 \quad (4)$$

where x_i is the i th training instance, y_i the corresponding label, and f is the network's feed-forward mapping.

Starting from an initial guess θ , Stochastic Gradient Descent (SGD) iterations are applied to gradually reduce J using the update

$$\theta \leftarrow \theta - \eta \nabla J(\theta), \quad (5)$$

where the step size η is the *learning rate*. The gradient ∇J is calculated using the *back-propagation algorithm* (Jing et al., 2012). All standard software frameworks provide an auto-differentiation module, as long as J is differentiable almost everywhere. Since the training set is large, SGD reduces gradient computation time by calculating ∇J only approximately on a *mini-batch* of training examples. Thus loss reduction is not monotonic and contains stochastic noise (Fig. 5B) [19, Chap. 8]. SGD converges to a local minimum. Convergence may be slow and require up to hundreds of *epochs* (passes over the training set) [19, Chap. 8]. Batch computation increases efficiency via GPU parallelism; the mini-batch size is chosen based on a trade-off between model performance and GPU memory capacity (Keskar et al., 2017).

Training and optimizing a neural network on a data set is a somewhat of an art. The practitioner can experiment with, vary, and substitute different elements to improve training time and the final model accuracy:

- Varying the number of layers, neurons (units) per layer, and the neuron connections, all of which comprise the network's *architecture*. Increasing the model capacity (number of learned parameters) is a double-edge sword: it can boost accuracy, but is also more prone to over-fitting.
- In particular, introducing *residual connections* or *skip connections*, connecting two layers that are farther apart in the network (i.e., non-consecutive). These are used to allow gradients to flow through a network directly without passing through non-linear activation functions, to mitigate training instability or slowness due to exploding or vanishing gradients. ResNet (He et al., 2015) is a popular architecture that demonstrates this training speed-up in pattern recognition applications.

Table 1 Some of the top neural network MNIST hand-written digit classification results, which surpass human performance.

Network	Prediction accuracy	Learned parameters
Branching/merging CNN with capsules (Byerly et al., 2021)	99.87	1,514,187
Efficient-CapsNet (Mazzia et al., 2021)	99.84	161,824
SOPCNN single model (Assiri, 2020)	99.83	1,400,000
Human (LeCun et al., 1995)	≈ 99.8	—

More results are available at [Anonymous \(2021\)](#).

- Training using different optimization algorithms (SGD; momentum-based methods, such as Adam ([Diederik, 2017](#))) and varying the learning rate reduction schedule to speed-up convergence.
- Adding data augmentation, drop-out layers, weight decay and loss regularization terms to avoid over-fitting in case of very large networks ([Goodfellow et al., 2016](#)).

As training on large benchmarks (e.g., ImageNet) may require weeks and/or many GPUs, many pre-trained models are available for download and use (e.g., [Koh, 2021](#)) ([Table 1](#)).

Convolutional Neural Networks

A Convolutional Neural Networks (CNN) is a specialized network for processing data with a known grid topology, for instance, time-series data (1D grid of samples) or image data (2D grid of pixels $\times$ #channels) [19, Chap. 9]. With the new reality shaped by COVID-19, remote testing and proctoring are taking center stage. Image processing tasks such as tracking a test subject's eye movements, or even merely classify when they appear on camera or not, are becoming crucial, and CNNs are a powerful tool to perform such tasks.

CNNs are frequently used in image and pattern recognition especially because they exploit the geometry to reduce the computational complexity of fully-connected DNNs. For instance, a fully-connected layer for a small image of size 100×100 has 10,000 weights *per neuron* in the second layer. In contrast, CNN layers consist of a set of learned *convolution kernels*, which have a small receptive field but extend through the full depth of the input volume [19, Chap. 9]. As each neuron is connected to a small image region (e.g., 3×3) of input neurons, layers represent features of increasingly larger scales ([Fig. 6](#)).

Software frameworks

Python has emerged as the dominant programming language for machine learning and data science. Notwithstanding, there are plenty of alternatives, from the traditional R, C/C++, Java, to the newer Scala and Julia ([Gossett, 2021](#)).

Fig. 6 A typical Convolutional Neural Network (CNN) architecture. A multi-scale feature representation is first extracted in convolutional layers (from edges to corners to object parts to entire objects). Fully-connected layers then perform the abstract object classification. Reproduced from [Developers Breach \(2021\)](#).

```

# Import needed packages.

# Compute the average accuracy and loss over all test images.
model.eval()
test_acc = 0.0
for i, (images, labels) in enumerate(test_loader):
    if cuda_avail:
        images = Variable(images.cuda())
        labels = Variable(labels.cuda())
    # Predict classes using images from the test set.
    outputs = model(images)
    _, prediction = torch.max(outputs.data, 1)
    prediction = prediction.cpu().numpy()
    test_acc += torch.sum(prediction == labels.data)
test_acc = test_acc / test_set_size
print("Test Accuracy: {:.3f}".format(test_acc))

```

Fig. 7 Python code example for measuring the prediction accuracy of the popular VGG CNN architecture (Simonyan and Zisserman, 2015) with pre-trained parameters on the CIFAR10 data set (Krizhevsky et al., 2010), using the PyTorch framework.

Python has become widely used for several reasons. It is easy to learn and use, prioritizes readability, and supports a rich ecosystem of libraries for data pre-processing and analysis (NumPy, SciPy, Pandas, scikit-learn), visualization (Matplotlib, Seaborn, Bokeh), and neural networks (the Facebook-developed PyTorch and the Google-developed TensorFlow, and Keras). Fig. 7 shows a basic NN implementation using PyTorch.

Applications to educational measurement

Automatic feature extraction: off-topic spoken response detection

In a speaking language proficiency test that elicits unconstrained spontaneous speech, especially if it is a low-stakes practice test, test takers may not provide good-faith responses if they are fatigued, unmotivated, distracted, etc. For instance, students may recite their response to a previous question (which would be off-topic), and this may help them reduce disfluencies and generate fluent speech. As a result, it may make it more difficult for an automated scoring system to provide a valid assessment of the proficiency of the speakers.

In (Lee et al., 2017), Min Lee et al. developed an off-topic response detection model in the context of automated scoring of non-native English speakers' spontaneous speech. The model consists of the three components shown in Fig. 8: a sentence modeling layer using *Siamese CNNs* (one for modeling questions, the other for modeling responses), a similarity distance calculation layer, and a fully-connected neural network layer. The model outputs an off-topic confidence score.

A data set of 100,000 spoken responses from a large-scale, standardized test of English speaking proficiency was collected. Each question asked to provide information about or opinions on familiar topics, and covered diverse topics: classroom activities, education and learning, and jobs, and work. The responses were converted into word hypotheses using an Automated Speech Recognition System (ASR). The NN was trained on 60% of the data and evaluated on 40%. The NN-based model had a 97% accuracy in detecting off-topic responses, compared with 94% for a baseline model trained using traditional ASR techniques. It also had a 3% higher recall (the fraction of responses flagged as off-topic by the model that were true off-topic responses). This illustrates the power of NNs in automatically extracting meaningful features from data. More generally, neuron activation values from the last few layers of a NN can be used as low-dimensional feature embedding for exploratory analysis (e.g., clustering).

Fig. 8 Siamese Convolutional Neural Network architecture for detecting off-topic spoken language responses. Reproduced from Lee et al. (2017).

Time-series modeling: automated essay scoring

Recurrent neural networks

In a traditional NN, all inputs (and outputs) are assumed to be independent of each other; but in some tasks that's not true. Predicting the next word in a sentence depends on which words came before it (Huang and Khan, 2021).

Recurrent neural networks (RNNs) (Miljanovic, 2012) are designed to recognize patterns in sequential data (text, genomes, stock prices, time-series sensor data). Two prominent RNN variations are Long Short Term Memory unit (LSTM) (Hochreiter and Schmidhuber, 1997) and Gated Recurrent Unit (GRU) (Chung et al., 2014). Unlike feed-forward neural networks, they have *feedback connections*, and can process not only single data points, but also entire sequences of data. They can be thought of having a “memory” which captures information about what has been calculated so far.

Fig. 9 depicts a basic RNN (cf. (Bao et al., 2017)).

1. x_t the input at time t , e.g., a one-hot vector of the t th word in a sentence for $t = 1, 2, \dots, T$. (In natural language processing, *one-hot vector encoding* (One, 2021) is a mapping of a word in a sentence into a vector of binary bits, such that each word corresponds to a unique vector representation.)
2. $s_t = \sigma(Ux_t + Ws_{t-1})$ is the hidden state at time t , which contains the network's “memory” and depends on the current input and previous hidden state via the activation function σ (e.g., a ReLU). As in a hidden Markov model, the memory depends mostly on recent values and gradually “forgets” older states.
3. $o_t = \sigma(Vs_t)$ is the output at time t . The final output o_T is fed to a loss function as in feed-forward networks. The difference is that in feed-forward networks, all the inputs and outputs are independent of each other, whereas in an RNN we generate different intermediate outputs o_t that depend on all inputs seen till that point $(x_1, \dots, x_t)$.

Fig. 9 A simple RNN architecture and its unfolded version. U , V and W are the weights of the hidden layer, the output layer and the hidden state, respectively. x_t and o_t are the input vector and output result at time t , respectively. Reproduced from Bao et al. (2017).

Table 2 The Quadratic weight Kappa (QWK) values of three automated essay scoring models on the ASAP data set.

Model	Prompts								Average
	1	2	3	4	5	6	7	8	
Score range	2 – 12	1 – 6	0 – 3	0 – 3	0 – 4	0 – 4	0 – 30	0 – 60	–
LSTM-CNN-att	0.822	0.682	0.672	0.814	0.803	0.811	0.801	0.705	0.764
SKIPFLOW	0.832	0.684	0.695	0.788	0.815	0.810	0.800	0.697	0.764
SBLSTMA	0.861	0.731	0.780	0.818	0.842	0.820	0.810	0.746	0.801

Reproduced from Liang et al. (2018).

Automated essay scoring

In (Liang et al., 2018), Liang et al. applied RNNs to Automated Essay Scoring (AES). AES helps reduce manual workload and speed up learning feedback. In that work, both the sample essays and rating criteria provided by domain experts were used as an input pair to a Siamese Bidirectional Long Short-Term Memory Architecture (SBLSTMA) model.

The model was evaluated on the Kaggle Automated Student Assessment Prize (ASAP) benchmark data set against two state-of-the-art baselines: SKIPFLOW and LSTM-CNN-att, a recurrent convolutional neural network (Dong et al., 2017). ASAP contains eight prompts, each of which is a different genre.

The SBLSTMA outperforms both baseline models (LSTM-CNN-att and SKIPFLOW) by approximately 5% on average Quadratic weight Kappa (QWK) (Sim and Wright, 2005) (cf. Table 2).

Other applications of RNNs in education include speech recognition, grammar learning, human action recognition, and in particular, natural language processing tasks such as semantic parsing and question answering, document summarization, and machine translation (Huang and Khan, 2021).

Transfer learning

Transfer learning (TL) is a machine learning approach aiming to exploit the knowledge retrieved from Problem A for improving the predictive performance of a learning model for a different but related Problem B (Tsiakmaki et al., 2020). TL is particularly useful when the available data for B at hand is set is small, but there is plenty of data about A. For instance, knowledge gained while learning to recognize cars (A) could apply when trying to recognize trucks (B); similarly, understanding language in general (A) can inform understanding the sentiment in student essays (B). DNNs provide an attractive approach to TL: a pre-trained model on the generic task (say, language) serves as the initial guess. It is fine-tuned by only training the last few layers, typically the fully-connected layers, on the data set of the new task. This reduces the number of learned parameters to avoid over-fitting, reduce training time, and exploit the universal representations of lower-level constructs already learned in the earlier layers.

TL has become an emerging research area in ML for education. In particular, they allow building predictive models of student behavior. Two examples: (a) (Tsiakmaki et al., 2020) demonstrates that predicting student performance (or at least identifying students at risk of failure) in a course can be achieved with satisfactory accuracy, provided that data sets of students who have attended other related courses are available; (b) in a Massive Open Online Course (MOOC), predictive models of student behavior can support multiple aspects of learning, including instructor feedback and timely intervention. Notwithstanding, when student outcomes are yet unknown, models trained on historical data have poor prediction performance. In (Ding et al., 2018), an automated transductive transfer learning approach using a temporal organization of the MOOC click stream data. An LSTM neural network was used to generate embedding of the data.

Generative adversarial networks and content generation

A *generative model* is a method to learn the true data distribution of real world from a training set, and then generate new training instances with some variations.

Generative adversarial networks (GANs) (first introduced by Goodfellow et al. (2014)) have dramatically advanced AI content generation. A GAN is a pair of neural networks, a *generator* and a *discriminator*, contesting with each other in a zero-sum game. The generator $G(z)$ learns to map random inputs z from a latent space to a particular data distribution of interest, while the discriminator $D(x)$ learns to discriminate between instances from the true data distribution and candidates produced by the generator.

The generator's training objective is to increase the error rate of the discriminator (i.e., to "fool" the discriminator network by producing fake synthesized instances that appear to have come from the true data distribution). The discriminator's training objective is to accurately predict whether the input x is real or generated (a binary classification) (Huang and Khan, 2021).

After training, the generative network can then be used to create new plausible samples on demand. GANs have been extremely successful in generating photographs of human faces; realistic cartoon characters; image-to-image translation; text-to-image translation; 3D object generation; and more (Brownlee, 2021). The next generation of learning and assessment systems will greatly

benefit by these advances. For instance, a game-based adaptive testing environment may need generate items and objects on the fly based; a collaborative learning environment may feature a computer-generated agent whose appearance and content are generated by GANs.

Summary

- Machine learning is a sub-domain of artificial intelligence, which focuses on the use and development of computer systems that can learn from examples. Parameters and data structures are automatically adjusted to optimize an objective function (a performance on a task), based on training examples. These structures learn patterns in the data that generalize to examples not seen before by the system.
- Machine learning includes supervised learning (which uses data labels), unsupervised learning (no labels/exploratory), semi-supervised learning (only part of the data is labeled), and reinforcement learning (operating against an adversary).
- Deep learning is a particularly popular family of machine learning methods that uses artificial neural networks, which have outperformed competing algorithms on many pattern recognition, natural language processing, and decision-making tasks.
- A neural network comprises of a sequence of layers, each containing many neurons. The strength of connection between neurons is updated during the learning process. Layers can either be convolutional or fully-connected. Training is performed using an optimizer such as stochastic gradient descent; open source Python implementations such as PyTorch and Tensorflow are typically used to train and test.
- Neural networks have been applied with great success to educational measurement tasks, including off-topic spoken response detection, time-series modeling, automated scoring of structured and essay responses, and content generation.

Future directions

ML and NN will likely continue to influence educational measurement, perhaps more than ever. And will influence educational measurement. Detecting sentiment, argumentation and cheating in essays might utilize features generated by powerful language models such as GPT-2 and GPT-3 (Brown et al., 2020). Novel Item Response theory (IRT) that use deep knowledge tracing models relying on time-dependent neural networks have been suggested (Converse, 2021).

Under the hood, field-agnostic fundamental research on better NN training algorithms, outlier identification, and increasing accuracy, has been booming, and will continue to rapidly evolve (Perez et al., 2020).

Glossary

Causal studies A type of research study designed to determine whether one or more variables actually cause changes in one or more outcome variables

Control group The group that does not receive the intervention within a research study

Correlational studies A type of research study that involves relating two or more variables without inferring causal relations

Descriptive studies A type of research study that involves the collection of data to simply describe a phenomenon

Internal validity The extent to which a researcher can accurately state that the independent variable caused the changes in the outcome variable(s)

Intervention group The group that receives the intervention within a research study

Exposure A variable (e.g., an intervention, a policy, another phenomenon) to which a unit (e.g., a person, a school, a community) is subjected that is theorized to cause change in one or more outcomes. Exposure may occur randomly or non-randomly

Exogenous Describes something that is unrelated to characteristics or qualities of a unit (i.e., random and/or external)

Endogenous Describes something that is related or attributable to internal qualities or characteristics of a unit (i.e., systematic)

Observational study A research design in which assignment to intervention or control groups is not done by random assignment. These studies may also be referred to as quasi- or non-experimental designs. Observational studies are more inclusive of all non-randomized studies, including studies designed to detect causal effects or correlate two or more variables

Random assignment A process or procedure in which units are assigned to the intervention or control group by a random process

Randomized experimental design A research study in which assignment to intervention or control groups is done by random assignment

Single-case design Studies involving one or a small number of individuals that are exposed to different treatments over time. Repeated measures are taken on each person and relations of repeated measures to changes in treatment are analyzed

“What works” has always been the primary question underlying educational research, and no more prevalent has that question been than since the rise of “education science” in the last 20–30 years. In the United States, much of this field of education science gained traction because of policy initiatives in the early 2000s through the No Child Left Behind (NCLB) legislation to systematically determine effective practices and use assessment as an accountability mechanism to promote more effective instruction. Many research and accountability efforts had been in place in the US and elsewhere prior to this; however, NCLB was one of the largest scale education policy initiatives at the time and promoted international attention to educational research as a quantitative science.

Like other social sciences concerned with the influence of policies and exposures (e.g., economics, epidemiology, sociology) on social outcomes, identifying what specific practices, curricula, and policies in education promote high-quality education and student outcomes is a complex causal question. In addition to having socially and organizationally complex theoretical relations in an education system, the specific statistical analyses used to examine these questions are directly linked to the theories and practices of determining educational effectiveness. Thus, in addition to articulating clear theories and hypotheses about effective educational practices and policies, education researchers must adhere to a set standards of sound research design and analyses. The goal of this

entry is to (a) discuss the importance of research in education, (b) outline the legal and professional guidelines for research in education, and (c) provide an overview of popular designs and statistical techniques used in education research, particularly those used for causal inference.

The United States in the early 2000s saw a massive push to establish an evidence base for effective educational practices after years of evolving and growing calls for evidence in education (see Eisenhart and Towne, 2003, for historical perspective of the evolution of the definition of scientifically-based education research in NCLB). The tension between the policy initiatives calling for evidence-based practices and the perceived lack of rigor in education research promoted a more scientific perspective in the assessment, testing, and promotion of evidence. This was further legitimized through federal funding and organizations to promote education science as an interdisciplinary field (i.e., U.S. Department of Education's Institute of Education Science).

Experimental design and statistical procedure considerations

Randomization to conditions (i.e., experimental designs) have typically been viewed as the “gold standard” of causal inference. That is, when an intervention is properly designed to sample and then randomize participating individuals or units to treatment(s) and control conditions (in addition to using appropriate statistical analyses), it is clear to infer that the intervention(s) caused observed changes relative to the control group. The sampling properties of that design and the statistical analyses used allow inference as to whether that observed effect is meaningfully different from zero.

Standards for experimental designs in education research have become increasingly rigorous as new methods are developed and tested. Perhaps the most well-known standards of research in education have been developed at the U.S. Department of Education's Institute of Education Sciences (IES), particularly IES's What Works Clearinghouse (WWC; <https://ies.ed.gov/ncee/wwc/>). WWC provides not only practitioner and researcher resources on evidence-based practices but also procedural and design standards for randomized, observational, and single-case design research. WWC's Standards Handbook (2020a) and Procedures Handbook (2020b), now in their fourth editions, provide clear and detailed information regarding the design and analysis of educational experiments and observational studies. Likewise, Kratochwill et al. (2010) developed WWC's Single-Case Design Technical Documentation (2010) that provides information regarding the design and analysis of single-case research.

Research designs

Detailed and technical information on all relevant research designs in education is outside the scope of this entry. We provide a broad overview of relevant (a) observational and (b) experimental designs in education. However, unlike much of the other work in education, we do not draw distinctions between causal and non-causal studies. Rather, we focus on distinguishing between experimental versus observational, regardless of whether causal inferences are warranted. We take this approach for two primary reasons.

First, causal inference is based on a set of assumptions, not a particular design. Randomization is not immune to bias or failures to infer causation. Likewise, observational studies can meet assumptions needed to infer causation with crafty identification of temporal exposures or mechanisms by which exposures are induced and/or advanced statistical methods that help meet assumptions for causal inference. We also believe that few, if any, questions in education are truly non-causal. Instead, purely descriptive or correlational studies can provide a foundation for understanding key relations that aid in theory development and understanding context. Although descriptive and correlational questions might not, on their own, tell us whether A causes B, they might tell us why A and B matter and how causal questions can be addressed in future studies.

Second, the distinction between causal and non-causal studies further obfuscates the assumptions of causal inference in all studies and reinforces the idea that large-scale, randomized studies are the only way to meaningfully assess causal effects. Of course, experimentation offers the most straight-forward way to say whether A causes B. However, that does not always require randomizing individuals to groups, nor does it always require group designs at all. Moreover, randomization may not be feasible or ethical in some cases. For example, epidemiological work has recently shown that an ideal randomized experiment (a “target trial”) can be emulated under certain conditions with observational data, potentially alleviating the need to design an experiment and collect new data (Hernán and Robins, 2016). Breaking down distinctions between causal and non-causal studies, we believe, will help researchers critically assess assumptions of causal inference, even for studies that are randomized and those that do not involve large group comparisons.

Below, we first introduce some key assumptions for causal inference (internal validity) before describing descriptive, correlational, and causal research in observational studies. Then, we describe group-randomized experiments and their common designs. Finally, we introduce single-case designs.

Internal validity and causal inference

Internal validity is the extent to which a design meets assumptions necessary to infer causal relations between one or more independent variables and one or more dependent variables. The primary rationale for conducting randomized experiments is that the nature of randomization alleviates many (but not all) internal validity problems. Randomization to conditions ensures that differences between conditions are attributable only to actual differences between conditions. This is related to an assumption called *exchangeability*: Person A in the control group and Person B in the treatment group could be exchanged with no consequences except for a difference in their outcomes due to the treatment(s). Randomization ensures this can be easily met. Many observational studies make it more difficult to assume exchangeability. Thus, some observational studies have a similar assumption called *conditional independence* or *ignorability*: conditional on certain factors (e.g., control variables), treatment assignment is essentially random. The methods by which conditional independence can be met are statistically technical and beyond the scope of this entry. Regardless of the presence of randomization, other key assumptions for causal inference are positivity and consistency. *Positivity* means that everyone has a non-zero probability of treatment exposure. *Consistency* means that the observed treatment is the same for everyone and independent of everyone; one person's treatment is the same as the next and they do not affect each other.

A simple example of exchangeability/conditional independence, positivity, and consistency can be demonstrated using covariates in an observational study. Students are nonrandomly assigned to either a math intervention group or a control; everyone has a non-zero chance of receiving either condition (i.e., positivity), but some process determines some students are more likely than others to get one of the two conditions. The intervention is administered individually in the exact same way to all participants. It is assumed that there is no cross-over between conditions (i.e., students in the control group would not affect the intervention group and vice versa; consistency), and students in the intervention or control do not affect the outcomes of other students in the same group (i.e., no interference). A researcher collects a large set of demographic and prior achievement data as well as interventions status and the outcome variable. The researcher might assess the difference in outcomes between groups while controlling for the background variables. Under strong assumptions, it might be possible to assume that the nonrandom treatment is essentially random once it is conditioned on the covariates, thus making it easier to assume that observed differences between conditions are due to the effect of the intervention. In reality, conditional independence, positivity, and consistency cannot be measured directly, and the researcher must try to determine how much these concepts influence their design.

Exchangeability and conditional independence are inherently tied to the selection mechanism into treatment. [Shadish et al. \(2002\)](#) offered clear definitions for nine factors of internal validity, with selection being a primary factor. In a randomized experiment where all individuals adhere to their assigned treatment condition, the only mechanism of selection into treatment is the randomization; randomization is an *instrument* determining treatment exposure. In observational studies, there may be other non-random instruments that determine exposure to a treatment (hence *instrumental variables* analysis). In other cases, the selection mechanism might be unknown and/or one or more groups can be observed longitudinally prior to and following exposure to a treatment. Observing variables over time helps address temporal precedence, which can also help understand selection processes into treatments or mechanisms of exposures.

History and maturation are also important. Processes acting simultaneously with the treatment may make inferences about a treatment ambiguous (i.e., history), and processes that naturally change over time may be confounded with a treatment (i.e., maturation). Maturation may occur naturally, but this idea is also related to testing effects, whereby being measured on an outcome systematically changes subsequent measurements. Similarly, the measures themselves may take on different characteristics (or be changed by researchers in a study) across time or groups, which is called instrumentation. Regression to the mean can also conflate causal effects, as extreme scores are more likely to converge toward the average. Missing data (e.g., attrition), if it occurs for systematic reasons related to the measurements or the treatment itself, may introduce bias, as those remaining in the study or those who provided data might represent certain participant characteristics that conflate treatment assignment with outcomes. The ninth internal validity threat [Shadish et al. \(2002\)](#) discussed is the potential for these factors to add to or compound one another. These threats are not mutually exclusive.

Importantly, randomized experiments are not immune from these threats, and these threats can just as easily add to or compound each other in randomized or observational settings.

Thus, although successful randomization helps mitigate issues of selection or temporal precedence, the threats of history, maturation, regression, missing data, testing, and instrumentation can all work independently or together in threatening the validity of a randomized design as well as observational studies. Thus, although successful randomization helps mitigate issues of selection or temporal precedence, history, maturation, regression, missing data, testing, and instrumentation can all work independently or together in threatening the validity of a randomized design.

Descriptive and correlational studies

Descriptive and correlational studies are primarily characterized by their inability to meet the necessary assumptions of causal inference in addition to the goal of the study. Descriptive work may not (and likely cannot) meet assumptions of causal effects, but that is not the goal of descriptive studies. These studies seek to highlight levels, trends, and contexts of certain variables. For example, developmental psychologists might seek to describe the level, trend, shape, and variability of a variable over time, in addition to the context in which the variable was measured. This is important work describing how a variable changes over time, but it likely makes no inferences regarding the causal process of growth or the relations of growth to other variables.

Correlational studies might extend or supplement descriptive and causal studies by articulating hypotheses about the extent to which two or more variables are related and why. A specific statistical analysis is neither correlational nor causal (these differences depend on assumptions and design); however, researchers might use a regression analysis to determine the magnitude of relations between students' social-emotional-behavioral well-being and academic achievement. Researchers might be interested in these well-being and achievement relations when controlling for a variety of variables, yet that study still would not likely warrant clear causal inferences just by controlling for potential confounders. Nonetheless, it may inform theory as to why and to what degree social-emotional-learning relates to achievement, which then may help other researchers and practitioners more clearly articulate underlying causal relations.

Causal studies

Causal studies may or may not differ in design and data collection procedures from descriptive and correlational studies. Randomized experiments, of course, would differ drastically from a purely correlational study. In reality, descriptive, correlational, and causal questions can all be addressed with similar data. For example, extant data sources such as administrative records or non-intervention secondary datasets from governmental or independent sources may lend themselves to purely descriptive, correlational, or causal questions. The tenability of causal inferences depends solely on the assumptions that can be made about the design and analysis, which applies to randomized and observational settings. We divide our discussion of causal questions into (a) randomized designs and (b) observational designs. In both sections, we attend to both large-*N* and single-case designs.

Randomized designs

Randomized group designs consist of randomizing many units (e.g., individuals, schools, communities) to different conditions. Many different design configurations can be used depending on the unit of randomization. Below, we review a few popular designs.

Factorial designs

Factorial designs can take place with any level of analysis (e.g., people, groups, organizations). Factorial designs consist of two or more categorical variables; only one categorical variable would simplify a factorial design into a one-way design. With multiple conditions, their interactions, and potentially repeated measures, factorial designs can easily become complex, necessitating caution when making many comparisons to avoid Type 1 errors and planning adequate sampling to ensure statistical power. More complex analysis techniques to account for the many different sources of variance in large factorial designs in education are advancing, however, such as Bayesian methods (Gelman et al., 2012; Kassler et al., 2020).

As an example, 200 students might be randomized to four conditions that are combinations of Treatments A and B. Individuals could receive Treatment A (treatment or control) with or without Treatment B (treatment or control). This is a 2×2 factorial design where Treatments A and B are crossed factors (i.e., both treatments appear in all levels of the other treatment). We simulated data for this design, the values of which are presented in Table 1. In this design, there are a number of different estimates that might be of interest to a researcher. For example, a researcher might be interested in computing the effects of Treatment B at each level of Treatment A (called simple effects), or a researcher might wish to examine whether the treatment effect of Treatment B is larger at one level of Treatment A as compared to another. Main effects would include comparing marginal means of the treatment and control groups (average values) across all other treatment values.

Factorial designs can be crossed, partially crossed, or nested. In a fully crossed design, all values of each factor occur in all levels of other factors. A partially crossed design is one in which only some factors are crossed. Finally, a nested design is one in which levels of one factor only occur in certain levels of another factor. For example, students might be randomly assigned to receive one of two interventions, but within each intervention, there are two different kinds of intervention settings: within one intervention condition, students are randomly assigned to one of two intervention settings. In the other intervention condition, students are randomly assigned to one of two different settings. The nested factorial design is closely related to what is commonly observed in applied research where classrooms are nested in schools: the same classroom cannot appear in different schools.

Blocked design

A blocked design occurs when individuals are randomized to conditions within blocks. These blocks are typically meaningful units of analysis, and this within-block randomization helps control for between-block variability that would not be of substantive interest to the study. However, blocking can leverage existing groupings to ease implementation of treatment allocation (using

Table 1 Means by condition for 2×2 factorial analysis of variance example.

		Condition B <i>M</i> (<i>SD</i>)		Marginal means: condition A
		Treatment B	Control B	
Condition A <i>M</i> (<i>SD</i>)	Treatment A	49.6 (10.6)	54.6 (11.2)	52.1
	Control A	51.2 (13.3)	49.7 (9.1)	47.95
	Marginal means: condition B	50.4	49.7	

Note. Data generated using the *faux* package (DeBruine, 2021) in R (R Core Team, 2021).

schools as blocks being a prime example). Typically, the blocking variable is included as a control variable when analyzing a randomized blocked design. As an example, students might be randomized to treatments within classrooms or schools. Then, the classroom or the school is accounted for in some way when analyzing the intervention effects. Blocking can be used with any grouping variable, however, especially if that grouping variable would be meaningful to account for when implementing a treatment. For example, a treatment might be randomized within grade levels or age ranges to account for variability across age levels. This would be a natural choice when it is assumed the blocking variable might relate to the outcome but not in a way that is of interest to the study. A blocked design could easily be incorporated within a nested, partially, or fully factorial design. Typically, the blocking factor in a blocked design is not of substantive interest because the goal is to remove variation in the outcome that could be attributed to the blocking variable. As a result, blocking can increase statistical power to detect a treatment effect relative to the same experiment conducted without blocking.

Cluster-randomized design

A cluster-randomized design (CRD) involves the randomization of existing groups to treatment conditions. In education, the most common example of the CRD is the randomization of classrooms or schools to treatment conditions. This differs from the blocked design in that the higher-level unit (e.g., teachers and/or schools) is of substantive interest because it is the unit assigned to treatment condition, whereas blocking variables in blocked designs are frequently not of direct interest to the study. However, CRDs can also be blocked (e.g., randomizing teachers within schools to treatment conditions).

CRDs inherently involve nesting of units within one or more higher-level groupings (e.g., students nested in classrooms and schools). This nesting creates a correlation among units within a higher-level grouping (e.g., students' achievement within a school possesses similarity for a variety of reasons). Nesting requires special care when analyzing data, and although nesting could apply to many different factorial and blocked designs, the nesting is an explicit component of CRDs. Multiple methods can be used to handle nesting in data, including multilevel modeling, cluster-robust standard error estimation, fixed effects estimation (e.g., including dummy codes for each higher-level grouping), generalized estimating equations (GEE), and design effects (Huang, 2018; McNeish et al., 2017), although multilevel modeling and cluster-robust standard error estimation tend to be the most prevalent in education when analyzing cluster-randomized trials.

Nesting is important to take into account because the correlation among units within groups can bias downward the estimation of variability if that correlation within units is ignored. The methods mentioned above all take into account nesting but do so in very different ways. If one is interested in estimating the variance in the outcome between higher-level groupings in a CRD, then multilevel modeling should be used. Cluster-robust estimation, GEE, and design effects all seek to correct the variance in the presence of clustering but do not model the variability across higher-level groups (see McNeish et al., 2017). We refer to the reader to McNeish et al. (2017) and Huang (2018) for further discussion of these modeling issues when analyzing nested data.

Another important implication of the CRD is that the correlation among units within groups reduces the statistical power to detect a treatment effect. The sample size in a CRD needs to be increased to obtain the same level of statistical power that one might have with an individually-randomized trial. This occurs because the correlation among units (e.g., students) implies less independence of outcome values within groupings, so outcome data within units are less unique than they would be if treatment conditions were allocated at the individual level. This dependence makes it harder to detect an effect because each data point is not contributing as uniquely in a CRD as compared to treatments randomized at the individual level. Recent studies detail issues of power in CRDs in education, and we refer readers to these articles for more discussion of power issues in CRDs (Spybrook et al., 2016, 2020).

Single-case research designs

Over the last decade or so, significant developments have been made with respect to single-case research. SCDs are conducted on one or more (usually a small number) units. These units, frequently individuals, are followed over time, and the time period over which they are followed includes changing exposures to interventions or stimuli. Although there are many different kinds of single-case designs, we focus on three widely used types: ABAB/withdrawal designs, multiple-baseline designs, and alternating treatments designs. ABAB designs consist of two conditions that are sequentially implemented for an individual; the individual is exposed to A, then B, then A again, then B again. This could extend on for as many time periods as feasible. With multiple individuals, the sequencing of A and B phases can be randomized. This combination of randomization and replication helps rule out internal validity threats including maturation and history. Multiple baseline designs involve a baseline and a treatment phase (as well as a follow-up phase in some cases), and the baseline length is staggered and randomized across individuals. With alternating treatments designs, individuals typically receive a baseline phase with one treatment, a treatment phase in which treatments A and B are alternated between immediate sessions, and a post-treatment phase based on the relative effectiveness of the interventions in the treatment phase.

The key factor across all these designs is the emphasis on replication of treatments and phases across individuals, although some designs also allow within-person replication (e.g., ABAB designs). Randomization has become a core component of single-case designs (SCDs; Kratochwill and Levin, 2010), whereas for many years SCDs were considered quasi- or non-experimental. These advancements have led to significant improvements in the rigor of SCDs in a variety of ways. Just like with group designs, randomization helps establish that the treatment is not systematically related to specific participant or unit characteristics. In addition, replication helps establish whether other factors are systematically related to the treatment (e.g., maturation, history).

Observational studies

As aforementioned, observational studies can be anything that does not involve researcher manipulation of treatment assignment. When seeking to identify causal effects in an observational setting, researchers are frequently interested in an intervention, policy, or phenomenon that is theorized to impact one or more outcomes. Often, mechanisms of exposure to those factors are nonrandom. Individuals may self-select into a treatment (or others may select them for treatment), or they may be exposed to a treatment in their setting due to treatment occurring at a context level (e.g., schools implementing curricula). Random exposures that are not created by a researcher are also possible in observational studies, such as lottery studies. For example, lottery enrollment is frequently used for dual-language education programs, which can be used to estimate the effects of dual-language education on outcomes (Steele et al., 2017). Importantly, the method of analyzing the observational study should align to the context of the treatment. Below, we briefly review some of these methods that are used to assess causal effects in observational settings. All of these methods can be combined, and sometimes that is a necessity for answering a causal question with observational data.

Regression discontinuity

Regression discontinuity designs (Lee and Lemieux, 2010) involve the use of a variable that determines assignment to conditions as a means of obtaining causal inferences. For example, a cut score might determine the placement of individuals into educational programs (e.g., Umansky, 2016). The variable creating the discontinuity (usually called the running variable) can be controlled for, which helps reduce any additional confounding between the treatment and the outcome that is due to the running variable. In education research, discontinuities frequently occur based on test scores. Even with a nonrandom running variable, individuals just above and just below the cutoff are likely to be very similar, so at the cutoff, a discontinuity design emulates a randomized experiment. Inferences about the causal effect that the discontinuity has are less tenable as one moves further away from the cutoff. As a recent example, Bonilla et al. (2021) examined how a high school ethnic studies class impacted long-term academic outcomes by using the grade-point average (GPA) cutoff that determined students' exposure to the ethnic studies class ($GPA = 2.0$). In their analysis, they controlled for a variety of demographic characteristics in addition to GPA, which determined treatment exposure.

Instrumental variable model

A frequent use of instrumental variables analysis is when there is an endogenous treatment or exposure (e.g., individuals self-select into treatment), but there may be another variable (or multiple) that predicts exposure or selection (the instrument[s]). Provided that the instrument does not also impact the outcome of interest (referred to as the exclusion criterion), specific statistical methods (often two-stage least squares) can be used to identify the extent to which the treatment or exposure impacted the outcome by using the instrumental variable to predict treatment exposure. Methods used in instrumental variable analyses help identify the part of the originally endogenous treatment that can be assumed to be *exogenous*, or external to specific characteristics of the units being investigated. Baiochi et al. (2014) provided a tutorial on using instrumental variables for causal inference in health settings, but these same concepts can be applied in education settings. Instrumental variable analysis can also be used when there is noncompliance to treatment assignment in randomized controlled trials and discontinuity designs. See Huang (2018) for an example of using instrumental variable analysis for noncompliance in experiments.

Weighting/matching

Often an instrument is not available, but treatment condition or exposure status is in addition to many other pre-treatment variables. In these cases, weighting or matching methods may be appropriate. These methods seek to create equivalent treatment groups by modeling the probability of treatment based on a large set of covariates. These variables would be used to predict treatment status, and the probabilities of treatment status (the propensity score) would then be used to match individuals across conditions. This helps establish the conditional independence assumption. Weighting methods simply transform the propensity score into a weight. Regression adjustment accomplishes a similar goal as weighting and propensity scores under certain conditions. We refer readers to Powell et al. (2020) for more on propensity score analyses in education.

Time-series designs

Time series designs involve following units (e.g., people, groups, organizations) over time. Interrupted time-series (ITS) designs occur when an intervention or exposure occurs during the time-series. In a typical ITS, the unit (or all units if more than one) in the time-series are exposed to the same intervention at the same time. Comparative interrupted time-series (CITS) designs involve the comparison of units that receive the intervention at different times or some units may not receive it at all. It should be noted that the CITS design also includes the difference-in-difference (DID) design, which compares the change in an outcome from pre-to post-exposure among an exposed group to a group that was not exposed (see Hall et al., 2021, for a recent example involving math achievement). Typically, the CITS design includes multiple pre- and post-exposure data points, whereas DID might include only one pre- and one post-exposure measurement. We refer readers to Somers et al. (2013) for more on CITS and DID designs and estimation for group-based studies. Importantly, single-case designs are, in fact, ITS and CITS designs. However, (C)ITS designs used in education and policy analysis frequently involve analysis at the group level and nonrandom treatment exposure, yet the principles of these designs are parallel to those of single-case designs.

Statistical analyses of causal designs

The statistical procedures available to researchers are innumerable and can be difficult to choose. More importantly, it is critical to align the statistical analyses with the data-generating process under investigation. This requires careful consideration of the design of the study and the properties of the independent and dependent variables under analysis. An incorrect application of a statistical procedure could ruin an analysis of even the best randomized design. For example, a study of the effect of a social-emotional curriculum on suspensions and office-discipline referrals might involve not only school-level assignment of the curriculum but a zero-inflated count outcome distribution (i.e., a large number of zeros relative to other values, as would likely be the case with suspension data). There are multiple ways to account for not only the nested nature of students in schools and school-level intervention assignment as well as the count outcome, and the choice of the appropriate analysis depends primarily on the inferences one would wish to draw from this study. Failure to account for the clustered design of the study as well as the type of outcome distribution could invalidate causal inferences about the intervention, despite a well-designed and implemented study.

Matching the design of one's study—including nesting, longitudinal data, and measurement scales—to the appropriate statistical analysis can be a challenging task in some cases. For example, some data might require nonparametric techniques or unique model specifications to account for difference sources of variance and dependence structures. In many cases, however, the analysis choices are a bit clearer. Using the 2×2 design described above, one would use analysis of variance (ANOVA)/linear regression.

In this design, one might be interested in the effects of either Treatment A (averaged across Treatment B) or Treatment B (averaged across Treatment A). One might also be interested in whether Treatment B works better in the presence of Treatment A or not, which is called an interaction effect or a moderation effect (i.e., Treatment A moderates or changes the effect of Treatment B). Using a two-way ANOVA that models the main effect of Treatments A and B as well as their interaction, one could conclude that Treatment A works (averaging across Treatment B), but Treatment B is not effective on average. However, Treatment B does work when it is combined with Treatment A, whereas it does not work without Treatment A.

The choice of this analysis is very clear as this design is the basic factorial ANOVA model. However, the decision for a particular analysis depends on a theoretical and practical understanding of the data-generating process being studied. Many designs have clear analysis decisions, but others do not, and these analysis issues should be understood as much before conducting a study as possible. When this is not possible, researchers should take care to select a method that comports with their theory and the inferences they wish to draw. For example, if Treatment A were a time variable (e.g., pre-test, post-test), the analytic model would need to change to accommodate the repeated observations of individuals in the study. With this addition, there might be many analytic choices, all of which offer strengths and drawbacks, although some may better align with specific theories than others.

Summary

The past two decades have been marked by continued growth in the amount of research conducted in educational settings and by growth in advanced research designs and analytical approaches. Within education, the expectations for what constitutes acceptable education practices have undergone a significant and meaningful transformation during this time with an increased emphasis in the application of doing what scientifically-sound research has clearly demonstrated to be effective practices.

Although randomized experimental designs are often held as the preferred method for determining evidence-based practice (e.g., by the U.S. Department of Education), it would be erroneous to automatically presume that such designs are the best design in all settings. Using such a design does not guarantee that various threats to the study's validity are not present. Instead, each of the research designs should be recognized to have relative strengths and weaknesses, with the results being interpreted with these in mind. In recognition of this, we described alternate research designs, including descriptions of observational versus experimental designs.

Glossary

Balanced sample A sample with the property that totals estimated from the sample for a set of variables equal the population totals for those variables

Cluster sample A sample in which each unit in the population belongs to a group (cluster), and the clusters are sampled according to the survey design

Nonprobability sample A sample that is drawn by means other than random selection. Samples that consist of units conveniently at hand are nonprobability samples

Nonresponse Failure of units selected for the sample to provide data on some or all survey items

Oversampling Sampling a population subgroup so that it comprises a higher percentage of the sample than of the population

Population The set of units for which estimates are desired

Probability-proportional-to-size sampling A sampling design in which the probability of selecting a sampling unit is proportional to the number of subunits it contains

Probability sampling A method of sample selection in which units are drawn using a random selection method and each possible subset of the population has a predetermined probability of being the sample that is drawn

Sampling weight The reciprocal of the probability with which a unit is selected to be in the sample. The sampling weight tells how many population units are represented by a unit in the sample

Simple random sample A sampling design in which every subset of n population units has the same probability of being selected as the sample

Stratified sample A sampling design in which the population units are partitioned into strata and a probability sample is selected from each stratum

Data collection from surveys

What percentage of fourth-grade children in Texas read at the level judged to be proficient by the state? What is the distribution of number of hours worked per week for public school teachers in a particular city? What percentage of elementary schools in a province employ a music teacher? How many students who take calculus in high school end up completing a college degree in mathematics, science, or engineering within six years of high school graduation? How satisfied are parents with their children's schools? What is the difference in literacy proficiency between adult men and adult women in a country?

These are all questions that may be addressed through taking a survey. While the research questions cover many different topics, their common feature is that they all are concerned with characteristics of a well-defined population at a specific period of time. The question asked is something that, given the operationalizations of the concepts, could be known exactly if every member of the population were accurately measured.

If the number of hours worked during the week of April 15 were ascertained accurately for every teacher in the city, then any statistic about number of hours worked per week would be known exactly for that population—the mean or median number of hours worked, the total number of hours worked for all teachers in the city, the percentage who work more than 40 hours per week, the difference in average working hours by gender and grade taught, and more.

The goal of the survey design is to obtain information from a sample that can be used to estimate the statistics that would be obtained if everyone in the population were measured, and to be able to assess the accuracy of the estimates.

The population is assumed to have N units, where N may be known or unknown. For the teacher workload survey, N would be the number of teachers in the city. For an assessment of reading proficiency among Texas fourth-graders, N would be the number of fourth-grade students. A sample of n units is to be taken from the N units in the population. The survey designer needs to decide what n should be, how units should be selected for the sample, and how information from the sample should be used to estimate characteristics of the population.

Probability and nonprobability samples

If the goal of taking a survey is to be able to describe features of the population of interest, the sample must be chosen in a way that allows the survey-taker to use the information from units in the sample to make inferences about units that are not in the sample.

Some samples consist of units that are easy to obtain or that are conveniently at hand. A sample that consists of persons who volunteer to participate in the survey (perhaps by clicking on a website), or a sample that consists of teachers who are personal acquaintances of the investigator, is a convenience sample. In a judgment sample, the investigator might deliberately select schools to be in the sample that are thought to be “typical” for the city.

Results from convenience or judgment samples are difficult to generalize to the population because no one knows whether statistics calculated from units in the sample reflect the characteristics of units not in the sample. Convenience samples often consist of the most accessible members of the population—for example, university students who pass by the library, or computer users who volunteer to take surveys—and it is unknown whether the sampled units are similar to less accessible units in the population. Judgment samples may reflect conscious or subconscious biases of the investigators. When samples consist of volunteers, a small group of persons with strong views can determine the survey results. Statistics calculated from convenience or judgment samples apply to the sample members; one must assume that the sampled units are like the nonsampled units in order to apply them to the population.

Probability sampling uses random selection to choose units to be in the sample, and thus eliminates many of the sources of bias that are associated with nonprobability samples, which do not employ random selection. In probability sampling, each subset of the population has a predetermined probability of being included in the sample. A randomizing mechanism such as a random number generator is used to select the sample according to those probabilities. Because the sample is selected randomly, the investigator need not worry that the results will be skewed from bias in selecting the sample.

Statistics from probability samples can be generalized to apply to the population without having to make assumptions about the unsampled units. In a probability sampling framework for inference, the probability distributions for statistics calculated from the sample are based on the distributions of the random variables that indicate which units are included in the sample. Suppose the population contains N units. Let π_i denote the probability that unit i is included in the sample, and let π_{ij} denote the probability that units i and j are both included in the sample. These probabilities give all the information that is needed to estimate population quantities and calculate the standard errors of the estimates. In a probability sample, it is assumed that every unit in the population can be selected for the sample (has $\pi_i > 0$).

The sampling weight of unit i in the sample S is $w_i = 1/\pi_i$, the reciprocal of the probability with which the unit is selected for the sample, and can be interpreted as the number of population units represented by a particular unit in the sample. Let y_i be a characteristic associated with unit i in the population. If a census were taken, y_i would be known for every unit in the population; when a sample S is taken, y_i is measured only for units in S .

The population total, $t_y = \sum_{i=1}^N y_i$, or population mean, $\bar{y}_p = t_y/N$, are often of special interest in a survey sample and are commonly estimated by

$$\hat{t}_y = \sum_{i \in S} w_i y_i \quad (1)$$

and

$$\hat{\bar{y}} = \frac{\sum_{i \in S} w_i y_i}{\sum_{i \in S} w_i} \quad (2)$$

Consider a survey in which 200 schools are randomly selected from a population of 2000 schools and y_i equals the number of music teachers in school i . With this sampling design, each school in the population has probability $\pi_i = 200/2000$ of being included in the sample. The weight of every school in the sample is $w_i = 1/\pi_i = 10$; each school in the sample represents itself

plus 9 other schools that were not selected for the sample. The weights for units in this sample sum to the population size, 2000. Here, calculating the estimated population total in [Eq. \(1\)](#) is equivalent to creating a new data set of 2000 pseudo-observations in which each sampled school's value of y_i is repeated w_i times, and then summing the number of music teachers in the new, replicated, data set. The sampling weights can be thought of as a way of using the sample to construct a pseudo-population whose characteristics are thought to resemble those of the original population.

Probability sampling designs

All probability sampling designs require that population units be selected randomly with the specified probabilities. Within that framework, though, many designs can be used. The design features described below can be used singly or in combination. For a probability sampling design with a sufficiently large sample, [Eqs. \(1\) and \(2\)](#) give approximately unbiased estimators of the population total and mean of a variable y . The variances of those estimators depend on the particular sampling design used. [Lohr \(2022\)](#) describes the theory of probability sampling and shows how to design and analyze surveys using the features described in this section. [Kalton \(2020\)](#) provides a concise, nontechnical summary of survey design and weight calculation.

Simple random sampling

In simple random sampling, each possible subset of the population of size n has an equal probability of being selected as the sample. Each unit in the population has sampling weight $w_i = N/n$. The example in the [Probability and nonprobability samples](#) section is a simple random sample of size 200.

Stratified sampling

For many education surveys, information is known about the population that can be used to make the survey design and estimation more efficient. In stratified sampling that information is used to divide the population into mutually exclusive groups called strata. The strata are often subpopulations of interest. A population of schools might be stratified by public or private status, urbanicity, and size; a population of students in a university might be stratified by gender, race, ethnicity, age, and field of study.

A stratified random sample is conducted by taking an independently selected simple random sample from each stratum. Suppose the population of 2000 schools contains 1500 public and 500 private schools. A proportionally allocated stratified random sample of size 200 would have 150 public and 50 private schools; each sampled school has weight 10, just as in simple random sampling. The difference is that the number of private schools in a simple random sample varies from sample to sample, while the stratified random sample is forced to have exactly 50 private schools. This forces the proportionally allocated sample to mirror the population with respect to the stratification variable of public/private status. If variable y is associated with the stratification variables, its distribution is likely to be more similar to the population distribution as well, and the standard error of $\hat{y}$ from a proportionally allocated stratified random sample of size n will usually be smaller than the standard error of the sample mean from a simple random sample of the same size.

Alternatively, a disproportional allocation may be desired in order to obtain a prespecified precision for certain strata. For example, one could sample 100 public and 100 private schools, so that the weight for each sampled public school is 15 and the weight for each sampled private school is 5. In this disproportional design, private schools are oversampled—that is, the proportion of private schools in the sample is greater than their proportion in the population of schools—and the weights must be used to obtain estimates that are unbiased for population quantities. The sampling weights are used in estimation to compensate for the oversampling. In this example, the sum of the weights for the sampled private schools is 500 and the sum of the weights for the sampled public schools is 1500. Even though the sample has equal numbers of schools of each type, the weighting brings them back to their proportions in the population.

In general, the more strata that can be formed, the better. A stratified sample with proportional allocation almost always provides more information per unit sampled than a simple random sample of the same size. Many surveys are stratified to the degree that 2 units are selected per stratum.

Balanced sampling

Sometimes more information is known about the population than can be accommodated in a stratified sampling design, or it is desired to have a sample that mirrors the population with respect to numerous variables. In the United States, for example, the College Scorecard system ([US Department of Education, 2021](#)) contains information on more than 1500 variables for each post-secondary education institution in the database, including information about number and demographic composition of undergraduate and graduate students, types of degrees offered, admission rates, retention and graduation rates, median student debt, tuition fees, early career earnings of graduates, and a wealth of other topics.

This information could be used to form strata for sampling. But stratification requires that each population unit belongs to exactly one stratum. Thus, a stratification by 5 categories of institution size, 3 categories of highest degree offered, public or private status, and high or low tuition results in 60 strata that are formed by the cross-classification of the stratification variables.

Balanced sampling (Tillé, 2011) allows a probability sample to be selected that reflects the distribution of each balancing variable individually (sometimes at the expense of the cross-classifications), and may be preferred to simple stratification when detailed information is available about the population before sampling. A balanced sample is selected so that

$$\hat{t}_x = \sum_{i \in S} w_i x_i = t_x \quad (3)$$

for each balancing variable x . Thus, a sample that is balanced by institution size, highest degree, public/private status, and high/low tuition will contain the same proportion in each category of those variables as the population. Balanced sampling has the additional advantage that the balancing variables need not be categorical—for example, if the admission rate is a balancing variable, then the sample will have the property that the estimated mean admission rate from the colleges in the sample will equal the mean admission rate of all colleges in the population. If an exact balanced sample cannot be achieved, Eq. (3) may be modified to require that $\hat{t}_x \approx t_x$.

A stratified sample is a special case of a balanced sample when the x variables are indicators for the cross-classified categories defined by the stratification variables. Balanced sampling is thus a generalization of stratified sampling that guarantees that the sample will mirror the population for each individual x variable considered for balancing. By omitting the cross-classifications from the set of balancing variables, a balanced sample can match the population on more characteristics than a stratified sample.

Cluster sampling

In simple and stratified random sampling, the individual is the unit that is sampled. Thus, to draw a stratified random sample of students, one would first construct a list of all students, divide the students on the list into strata, and then draw a simple random sample from each stratum. This may be feasible for sampling students within a single school or university, but may be impractical for drawing a sample from the set of all students in a province or country. Typically, in these situations, a cluster sampling design is used. A stratified sample of schools (clusters) is selected, and then all or a subsample of students are sampled from each selected school. Here, a school is the primary sampling unit (psu) that is selected at the first stage of sampling, and the student is the secondary sampling unit (ssu) that is selected at the second stage of sampling.

Students in the same school often share common environmental factors. They may live in the same area, learn from the same teachers, or have similar socioeconomic backgrounds. It would thus be expected that students in the same school would have more similar values of y than students selected randomly from the population of all schools. Thus, selecting a sample of n students through a cluster sample typically does not provide as much information as a simple random or stratified random sample of size n .

In a one-stage cluster sample, all ssus within a sampled psu are sampled. In a survey where the survey instrument is administered to every student within a sampled school (for example, if each student is given a paper or computer-administered assessment), a one-stage sample makes sense because there is little additional cost to sample all, rather than some, students in the school. For a more labor-intensive assessment (for example, if sampled students are given a medical examination or interviewed in person), it may be more cost-effective to use a two-stage cluster sample, in which a subsample of ssus is taken from each psu.

The sampling weights are determined by the probabilities of inclusion at each stage. In a two-stage cluster sample with schools as psus and students as ssus, the weight for student i is $w_i = 1/[P(\text{student } i\text{'s school is included in the sample}) \times P(\text{student } i \text{ is included in the sample of students from that school})]$.

While a cluster sample typically has less precision relative to a simple random sample of the same number of students, it is commonly used for education surveys because schools or classrooms form a natural sampling unit. Much of the expense for the survey comes from securing cooperation of sampled schools and ensuring that the instrument is administered at the school according to the survey protocols; in some cases, field investigators may need to travel to the school to work with school personnel or administer the instrument. Thus, a cluster sample is often less expensive or easier to conduct than a design that involves sampling students directly (which may not even be possible in the absence of a list of all students). A cluster sample of schools has the additional advantage that school-level or classroom-level effects and similarities can be studied.

The precision of estimates from a cluster sample depends primarily on the number of psus that are sampled. To obtain greater precision for estimates from a cluster sample in which students are subsampled from schools, it is generally necessary to sample additional schools as opposed to subsampling more students within a fixed number of sampled schools.

Probability-proportional-to-size sampling

The psus used in cluster sampling are often groupings that occur naturally such as geographic regions, communities, school districts, schools, or classrooms. The psus may vary greatly by size—some schools may have 3000 students while other schools may have 100 students. An equal-probability sample of schools gives a large school the same probability of selection as a tiny school, even though the large school contributes much more to the population total.

Instead of selecting psus with equal probabilities, many survey designs call for selecting them with probabilities proportional to their sizes. This selection is often done after the psus are grouped into strata to improve precision and ensure that large psus have high probability of being included in the sample; some very large psus may be selected with probability one so that they are guaranteed to be in the sample.

If schools are sampled with probability proportional to size and then the same number of students is selected from each sampled school, then each student in the population has an equal probability of being selected for the sample. This design has many advantages in practice. The large schools have higher probability of being represented in the sample, yet the workload of conducting interviews or administering assessments is approximately the same for each sampled school. If population totals of interest are roughly proportional to the size of the psu (for example, larger high schools might be expected to have a larger number of students who enroll in college than smaller high schools), then the probability-proportional-to-size sampling design will also produce estimates that have greater precision. If the number of psus in population is unknown before sampling, an estimate or a related measure of size may be used to assign the probabilities of selection.

Systematic sampling

In systematic sampling, every k th unit is selected from a list of population units. The starting point is chosen randomly. If the list is in random order, a systematic sample will behave much the same way as a simple random sample. Systematic sampling may produce biased estimates if the population units are arranged in periodic order: if, for example, men and women alternate in the population list and $k = 10$, the systematic sample will consist of either all men or all women.

Systematic sampling, however, can produce estimates with higher precision than simple random sampling if the population is sorted before sampling according to characteristics thought to be related to quantities of interest. It is often used for selecting students or teachers in the second or third stage of a cluster sample. Suppose that in a cluster sample of teachers, schools are selected with probability proportional to the number of students in the first stage of sampling. Within each sampled school, the teachers are listed in decreasing order of years of experience. Then a systematic sample of teachers within the school is guaranteed to contain teachers with a range of values for years of experience.

Stratified multistage sampling

Many large education surveys combine stratification with several stages of clustering. For a national survey, the first stage of sampling might select geographic areas of the country, the second stage might select school districts in the sampled areas, the third stage might select schools within districts, the fourth stage might select classrooms within schools, and the fifth stage might select students within the selected classrooms.

As an example, consider the sampling design structure for the 2019 Trends in International Mathematics and Science Study (TIMSS), a survey intended to provide information on student knowledge and skills in mathematics and science in countries around the world, with emphasis on measuring trends over time. Each participating country devises a design for sampling fourth-grade and/or eighth-grade students in the country, following the basic two-stage stratified sampling design described by LaRoche et al. (2020).

The first step for the basic TIMSS design is to construct or obtain a list of all schools containing fourth- or eighth-grade students. The schools may be placed into strata according to country-specific variables such as state or province, degree of urbanization, language of instruction, socioeconomic variables, or school scores on national examinations. Then schools are sampled within strata with probability proportional to size.

The stratification improves the precision of estimators and also allows specific types of schools to be oversampled if desired. In some countries, the list of schools is sorted by the stratification variables and a systematic sample of schools is selected from the sorted list, which forces an implicit stratification.

In the second stage of sampling, a fixed number of classes (usually one or two) is randomly selected from the set of classes for the target grade at each sampled school. All students in the sampled classes then participate in the assessment. Selecting a fixed number of classes in the sampled schools largely offsets the unequal probabilities of selection at the first stage and results in a sample of students in which each student has a similar probability of being selected for the sample and hence a similar sampling weight.

Standard errors of estimates from probability samples

The design features discussed above affect the precision of estimates from surveys. Estimates from a stratified sample with proportional allocation usually have smaller standard errors than estimates from a simple random sample of the same size; estimates from a cluster sample usually have larger standard errors than estimates from a simple random sample of the same size.

Standard errors can be calculated in multiple ways. Formulas for calculating standard errors of statistics from stratified and cluster samples, which depend on the inclusion probabilities π_i and π_{ij} , are given in Lohr (2022) and other sampling books. Standard errors for statistics such as regression coefficients can be calculated using linearization (Taylor series) methods.

Many surveys that employ a stratified multistage design use replicate weight methods to calculate standard errors. With these methods, which include jackknife, bootstrap, and balanced repeated replication, the variability among estimates calculated with

the replicate weight variables is used to compute standard errors of estimates. Valliant et al. (2018) give step-by-step instructions for constructing and using replicate weights.

Survey design and nonresponse

The sampling designs and estimators in the **Probability and nonprobability samples** and **Probability sampling designs** sections are constructed assuming that (1) every unit in the population has a positive probability of being selected for the sample (for example, all schools in the country are included in the list of schools from which the sample is drawn), (2) every unit selected for the sample provides data (there is no nonresponse), and (3) every unit provides accurate answers to the survey instrument (there is no measurement error and no missing data for items on the instrument).

Few surveys achieve this ideal. Survey samplers have a number of tools that can attempt to compensate for nonresponse and potential bias arising from nonresponse. These include adjusting the sampling weights of respondents so that they account for similar nonrespondents' share of the population as well as their own (weighting and calibration; see Särndal and Lundström, 2005) or substituting predicted values for the missing data (imputation; see van Buuren, 2018).

The best way to deal with nonresponse and measurement error is to try to anticipate and prevent them while designing the survey. Measurement error can be reduced through designing survey instruments that accurately and reliably measure the concepts of interest (Saris and Gallhofer, 2014). The choice of how to administer the survey can also affect measurement error: for sensitive topics such as cheating or drug use, a self-administered survey may elicit more accurate responses, while in other situations responses may be more accurate when the survey is administered by an interviewer who can explain the survey items (Dillman et al., 2014).

Potential nonresponse, too, should be considered during the survey design. A pilot study or previous surveys can indicate the anticipated amount of nonresponse. Designed experiments can be conducted to explore methods for improving response rates or for reducing nonresponse bias or measurement error. It may be desired to oversample strata that are anticipated to have low response rates.

Nonprobability samples

Under ideal circumstances, where every unit in the population has a positive probability of being selected for the sample and there is no nonresponse or measurement error, a probability sampling design is guaranteed to give estimates that are approximately unbiased and that have known precision. In some situations, though, it may be impossible or overly expensive to conduct a high-quality probability sample, or a nonprobability sample may better meet the research needs.

Convenience or judgment samples may provide useful information in some situations. Many psychology experiments, for example, are conducted on convenience samples of students enrolled in Psychology 101 classes. But to generalize beyond the students participating in the experiment, the investigator must assume that the experimental results observed for the college students will apply more generally. This assumption can often be tested only by repeating the experiment on other types of participants.

Sometimes probability samples are infeasible when it is desired to take a survey of a subpopulation that is relatively uncommon in the larger population, such as students who are recent immigrants or teachers who are military veterans. A probability sample of schools might yield relatively few students or teachers in the population of interest. But a respondent-driven sample, a nonprobability sample in which an initially recruited set of persons in the desired subpopulation then recruits other persons in the subpopulation to be in the sample, may yield a large sample of persons in the subpopulation of interest, even though it is not guaranteed to be representative or produce unbiased estimates. Gile et al. (2018) discuss how to calculate estimates from these types of nonprobability samples and assess their validity.

The main concern with nonprobability samples is that some parts of the population may be systematically excluded from the sample and that estimates calculated from the nonprobability samples may thus be biased. This may occur even if the nonprobability sample is extremely large. The mean squared error (MSE) for the sample mean $\bar{y} = \sum_{i \in S} y_i / n$ can be expressed as the product of three factors (Meng, 2018):

$$MSE(\bar{y}) = E[(\bar{y} - \bar{y}_p)^2] = E[\{Corr(R, y)\}^2] \times \frac{N-1}{N} \left(\frac{N}{n} - 1 \right) \times \sigma^2 \quad (4)$$

where $Corr(R, y)$ is the correlation between the variable of interest y_i and the variable R_i that indicates participation in the sample ($R_i = 1$ if unit i is in the sample and 0 otherwise), and σ^2 is the population variance of y . From Eq. (4), the MSE is low if there is little association between the value of y and being in the sample, if the sample accounts for a large part of the population (the second factor is 0 if $n = N$), or if the values of y in the population are all similar to each other (σ^2 is small).

For a simple random sample, the expected squared correlation between R and y is $1/(N-1)$, and it is typically of similar magnitude for other types of probability samples. Thus, in a simple random sample, $MSE(\bar{y}) \leq \sigma^2/n$; the precision of the estimate increases when a larger sample size n is taken—regardless of the population size.

In a nonprobability sample, however, even small correlations between y and participating in the sample can result in substantial bias that cannot be mitigated by taking a larger sample. A correlation of 0.05 is often considered to be small in the social sciences. But if the expected correlation between y and R is of that magnitude, so that $E[\{\text{Corr}(R, y)\}^2] \geq 0.0025$, then a sample of half the population has larger MSE for estimating the population mean than a simple random sample of size 400. Thus, with a modest correlation of 0.05 between y and the sample selection, a convenience sample of 500 million people from a population of one billion people provides less accuracy than a simple random sample of size 400 from the same population.

The accuracy of estimates from a nonprobability sample thus depends on the degree of correlation between the variables of interest and the sample selection mechanism. Tourangeau et al. (2013), summarizing results of studies about volunteer web surveys, found that even after weighting adjustments there were often substantial biases that could shift the estimates by 20% or more. On the other hand, if inclusion in the nonprobability sample is not related to the variables of interest, the nonprobability sample may produce valuable information at much less cost than a probability sample. The challenge for nonprobability samples is that, unlike in a probability sample with full response, the correlations between inclusion in a nonprobability sample and variables of interest—and hence the biases—are unknown.

Decisions for survey designs

The best survey design is one that fits the needs of the research. Sometimes it is desired to have highly accurate statistics that describe the entirety of the population. In that case, it may be desired to take a high-quality probability sample with adequate resources to follow up with nonrespondents. In other situations, particularly in preliminary stages of research, a nonprobability sample may provide the type of information needed to inform further investigations.

A number of decisions need to be made when designing a survey. The first involves whether a survey should be taken at all. It may be possible to answer the research questions (or modifications of them) with existing survey data or by combining data from multiple sources (National Academies of Sciences, Engineering, and Medicine, 2017). Flawed statistics from a convenience sample with high bias, or from a poorly conducted, high-nonresponse probability survey (which may have the same types of biases as the nonprobability samples discussed in the Nonprobability samples section) may result in more harm than having no statistics.

If it is determined that a survey is the best method for answering the research questions, the sample should be designed to give estimates with desired precision for the quantities to be studied, for the population as a whole and for subpopulations of interest. Information that is already known about the population can be used for stratifying or balancing the sample, or for oversampling certain subpopulations. If clustering is to be employed, simulation studies can provide information for evaluating candidate designs. Lohr (2022) describes methods for optimizing and evaluating prospective survey designs.

If the survey is to be repeated at different points in time, a repeated cross-sectional (independent samples are taken at each time period), longitudinal (the persons in the initial sample are followed over time), or panel (cohort samples are taken at different start times and followed for multiple interviews) design may be used. All of these designs allow the investigator to study changes in the mean levels of variables over time (for example, the average score in year 2 can be compared with the average score in year 1). Longitudinal and panel studies may be more complicated to conduct, but they also allow the researcher to study intra-personal changes over time (for example, the trajectory of tobacco product use in individual high school students).

Finally, the survey design should anticipate possible problems that may arise during implementation. Pre-survey experimentation and testing can help identify some of these problems. Sufficient resources should be set aside for following up with nonrespondents. The survey-taker should also, if possible, collect information in the survey that can be used later to adjust for nonresponse and evaluate nonresponse bias.

Continuous probability distributions are distributions that are used to describe continuous random variables. The values of variables observed in statistical applications are mostly discrete, often due to the use of rounded units. For example, the weight of a person is a continuous variable, but is typically measured in the nearest pounds or kilograms. Therefore, strictly speaking, continuous distributions may not be appropriate tools in statistical applications. That is one reason [Holland \(1979\)](#) was surprised by the tyranny of continuous models in a world full of discrete data. However, continuous distributions are convenient approximations of the reality, facilitating mathematical and statistical analysis ([Johnson et al., 1994](#)). For example, think of a random variable X that follows the binomial distribution (see the article on discrete probability distributions by Sinharay in this encyclopedia) with number of trials = 30 and success probability = 0.4. To compute the probability that X is less than or equal to 10 using binomial probability values, one has to sum 11 terms of the form $\binom{30}{x} 0.4^x 0.6^{30-x}$. However, if the investigator approximates the binomial distribution (a discrete distribution) by the normal distribution (a continuous distribution—described later in this article), the computation is much simpler as shown below

$$P(X \leq 10) = P(X \leq 10.5) = P\left(\frac{X - 30 \times 0.4}{\sqrt{30 \times 0.4 \times 0.6}} \leq \frac{10.5 - 30 \times 0.4}{\sqrt{30 \times 0.4 \times 0.6}}\right) = \Phi(-0.56)$$

where $\Phi(\cdot)$ denotes the cumulative distribution function (cdf) of the standard normal distribution and the addition of 0.5 to 10 denotes a “continuity correction”. Such approximations are satisfactory in several statistical applications. For example, while the probability $P(X \leq 10)$, computed from the binomial distribution, is 0.2917, the aforementioned normal approximation provides a value of 0.2881—so the approximation is quite accurate.

A key issue with a continuous random variable is that the probability is zero that it will take any specific value. However, there is usually a positive probability that such a variable will fall within an interval. While a discrete random variable has a probability mass function, a continuous random variable has a probability density function (pdf). The integral of the pdf over an interval is the probability that the continuous random variable will fall in that interval; The probability is known as the cdf of the variable when the interval includes all values smaller than or equal to a given value x .

In the following sections, several continuous distributions are discussed. For each distribution, its genesis, pdf, cdf, moments, estimation of the moments, methods to generate values of a random variable following that distribution, and relationships to other distributions (if any) are discussed.

Uniform distribution

The uniform or rectangular distribution with range (a, b) , often denoted as $U(a, b)$, has the pdf $\frac{1}{b-a}$ if $a \leq x \leq b$ and 0 otherwise. The cdf is 0 if $x \leq a$, $\frac{x-a}{b-a}$ if $a \leq x \leq b$ and 1 if $x \geq b$ otherwise. When $a = 0$ and $b = 1$, the uniform distribution becomes the standard or unit uniform distribution.

The mean of the distribution is $\frac{a+b}{2}$ and the variance is $\frac{(b-a)^2}{12}$.

For any continuous random variable Y , its cdf $F(y)$ follows a $U(0,1)$ distribution and $F^{-1}(R)$ has the cdf F for R following the $U(0,1)$ distribution. This property is used to generate random numbers from other continuous distributions starting from standard uniform random numbers (e.g., [Evans et al., 2000](#)).

The method of moments estimates of a and b are $\bar{x} - 3^{1/2}s$ and $\bar{x} + 3^{1/2}s$ respectively where $\bar{x}$ is the sample mean and s is the sample standard deviation. The maximum likelihood estimates of a and b are the minimum and maximum values, respectively, over the sample. To generate a random number x following a $U(a,b)$ distribution, one has to generate a $U(0,1)$ random number R , and then use the transformation $x = a + (b - a)R$.

The uniform distribution has found several applications as the prior distribution of the parameters of IRT models in Bayesian analyses. For example, in Bayesian IRT analyses, [Karadavut \(2019\)](#) and [Gao and Chen \(2005\)](#) assumed the prior distribution of both the examinee ability parameter and item difficulty parameter to be the uniform distribution between -3 and 3 .

Exponential distribution

The exponential distribution has been employed to model variables such as the time to decay of radioactive atoms and time to failure of components with constant failure rates.

The pdf of the exponential distribution is given by

$$f(x; b) = \frac{1}{b} e^{-x/b}, 0 \leq x \leq \infty$$

The mean of the distribution is b and the variance is b^2 . The maximum likelihood estimate of b is the sample mean.

A random number from the exponential distribution can be generated by generating a $U(0,1)$ random number R and then computing $-b \log(R)$.

[Scheiblechner \(1979\)](#) suggested the *latent exponential model* for modeling the response times of examinees on test items, where the mean parameter of the distribution is the sum of an examinee speed parameter and an item speed parameter.

Normal distribution

The uniform or rectangular distribution is arguably the most frequently used continuous distribution in statistics and in educational measurement. The normal distribution with mean μ and variance σ^2 , often denoted as $\mathcal{N}(\mu, \sigma^2)$, has the pdf

$$\phi(x; \mu, \sigma^2) = \frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{(x-\mu)^2}{2\sigma^2}} \text{ if } -\infty \leq x \leq \infty$$

The cdf is given by

$$\Phi\left(\frac{x-\mu}{\sigma}\right) = \int_{t=-\infty}^x \phi(t; \mu, \sigma^2) dt$$

The standard normal distribution is a special case of the normal distribution with $\mu = 0$ and $\sigma = 1$. The cdf of the standard normal distribution is given by

$$\Phi(x) = \int_{t=-\infty}^x \phi(t; 0, 1) dt = \int_{t=-\infty}^x \frac{1}{\sqrt{2\pi}} e^{-\frac{t^2}{2}} dt$$

Given $x_1, x_2, \dots, x_n$, which is a random sample of observations of size n from a normal distribution with mean μ and variance σ^2 , the method of moments estimates as well as the maximum likelihood estimates of μ and σ^2 are the sample mean $\bar{x} = \frac{1}{n} \sum_{i=1}^n x_i$ and sample variance $s^2 = \frac{1}{n} \sum_{i=1}^n (x_i - \bar{x})^2$, respectively. There exist numerous approaches for generating random draws from the normal distribution. A popular approach, that suggested by [Box and Muller \(1958\)](#), involves first simulating two random numbers X_1 and X_2 from a uniform distribution between 0 and 1 and then applying the transformations $Z_1 = \sqrt{-2\log(X_1)}\cos(2\pi x_2)$ and $Z_2 = \sqrt{-2\log(X_1)}\sin(2\pi x_2)$; Z_1 and Z_2 would be independent and follow the normal distribution with mean 0 and variance 1.

The normal distribution has found several applications in education. For example, in applications of item response theory (IRT) (see, for example, articles by Ackerman and Cai in this encyclopedia and [Hambleton and Swaminathan, 1985](#)), the examinee ability distribution is typically assumed to follow the normal distribution.

Lognormal distribution

If a random variable V has a normal distribution with mean μ and variance σ^2 , then e^V has a lognormal distribution with parameters μ and σ^2 . In other words, if a variable has a lognormal distribution, then its logarithm has a normal distribution. The pdf of the distribution is given by

$$f(x; \mu, \sigma^2) = \frac{1}{x\sigma\sqrt{2\pi}} e^{-\frac{1}{2}\left(\frac{\log(x) - \mu}{\sigma}\right)^2}$$

where x and σ are both positive. If X follows a lognormal distribution with parameters μ and σ^2 , then $Y = e^a X^b$ follows a lognormal distribution with parameters $a + b\mu$ and $b^2\sigma^2$.

The expectation and variance of the lognormal distribution are given by $e^{\mu + \frac{\sigma^2}{2}}$ and $e^{2\mu + \sigma^2}(e^{\sigma^2} - 1)$, respectively.

Using its relationships to the normal distribution, the parameters of the lognormal distribution from a sample $x_1, x_2, \dots, x_n$ of draws from the distribution can be estimated as

$$\hat{\mu} = \frac{1}{n} \sum \log(x_i), \hat{\sigma}^2 = \frac{1}{n-1} \sum (\log x_i - \hat{\mu})^2$$

The easiest way to generate random numbers from a log-normal distribution with parameters μ and σ^2 is to generate random numbers from a normal distribution with mean μ and variance σ^2 and then exponentiate them.

In some applications of Bayesian methods to IRT models, the prior distribution on the slope parameters is sometimes assumed to be a lognormal distribution. For example, the PARSCALE software program (e.g., see [du Toit, 2003](#)), which is used to fit IRT models by several operational testing programs, assumes a lognormal distribution as the prior distribution for the slope parameters. In addition, a popular model for response times (e.g., [van der Linden, 2006](#)) is based on the lognormal distribution.

Student's t distribution

The t distribution is often applied in testing hypotheses for normally distributed data. For example, for testing the hypothesis that the mean of a normal distribution is 0, the standard test statistic follows a central t distribution under the null hypothesis.

The pdf of the distribution is given by

$$\frac{\nu^{1/2} e^{-\delta^2/2}}{\Gamma(\nu/2) \pi^{0.5} (\nu + x^2)^{(\nu+1)/2}} \sum_{i=0}^{\infty} \Gamma\left(\frac{\nu+i+1}{2}\right) \frac{(x\delta)^i}{i!} \left(\frac{2}{\nu+x^2}\right)^{i/2}$$

where ν is the degree of freedom (df) and δ is the non-centrality parameter.

The mean of the distribution is $\frac{\delta(\nu/2)^{1/2} \Gamma((\nu-1)/2)}{\Gamma(\nu/2)}$ and the variance is given by

$$\frac{\nu}{\nu-2} (1 + \delta^2) - \frac{\nu}{2} \delta^2 \left(\frac{\Gamma((\nu-1)/2)}{\Gamma(\nu/2)} \right)^2$$

If the non-centrality parameter is 0, then the distribution is called a central t distribution that has mean 0 and variance $\frac{\nu}{\nu-2}$.

The t distribution has a much heavier tail than the normal distribution for small df. [Fig. 1](#) shows a comparison of the pdf of the Student's t distribution with 4 df against that of the standard normal distribution. The tail of the t distribution is heavier than that of the normal distribution.

For large df's, the central t distribution becomes close to the standard normal distribution. If X and Y are independent random variables and they follow the standard normal distribution and the χ^2 distribution with ν df, respectively, then $\frac{X}{\sqrt{Y/\nu}}$ follows the t distribution with ν df. The distribution of the square of a random variable that follows a central t distribution with ν df multiplied by ν is an F distribution with df's 1 and ν .

To generate a random number following the central t distribution with ν df, one can compute the ratio of a standard normal random number and the square root of Y/ν , where Y is a random number following the χ^2 distribution with ν df and both of these random numbers are generated independently of each other.

The t statistic, whose distribution under null hypothesis is the t distribution, has been widely used in education (e.g., [Zimmerman, 1997](#)). Other types of application of the distribution to education include [Fox et al. \(2014\)](#) where, in a Bayesian IRT approach, the prior distribution of the item parameters was assumed to be a t distribution.

Beta distribution

The beta distribution is used to model continuous random variables whose range is between 0 and 1. For example, in Bayesian analyses, the beta distribution is often used as a prior distribution of the parameter p (which is bounded between 0 and 1) of the binomial distribution. See, for example, [Novick and Jackson \(1974\)](#).

The pdf of the beta distribution is given by

$$f(x; a, b) = \frac{1}{B(a, b)} x^{a-1} (1-x)^{b-1}$$

Fig. 1 Plot of the pdfs of the standard normal, Cauchy and the Student's t distribution with 4 df.

where $0 \leq x \leq 1$, $a > 0$ and $b > 0$ are called shape parameters, and $B(a, b)$ is the beta function defined as

$$B(a, b) = \int_{x=0}^1 x^{a-1} (1-x)^{b-1} dx = \frac{\Gamma(a)\Gamma(b)}{\Gamma(a+b)}$$

where $\Gamma(a)$ is the gamma function defined as $\Gamma(a) = \int_{t=0}^{\infty} t^{a-1} e^{-t} dt$. Note that when $a = b = 1$, the Beta distribution becomes identical to the uniform distribution between 0 and 1.

The expectation of the beta distribution is $\frac{a}{a+b}$ and the variance is $\frac{ab}{(a+b)^2(a+b+1)}$. The method-of-moments estimates of the parameters a and b can be obtained by setting the above-mentioned mean and variance equal to the sample mean $\bar{x}$ and sample variance s^2 and solving them for a and b . The solutions in this case are defined only when $\bar{x}(1-\bar{x}) > s^2$ and are given by

$$\hat{a} = \bar{x} \left[\bar{x} (1 - \bar{x}) / s^2 - 1 \right], \hat{b} = (1 - \bar{x}) \left[\bar{x} (1 - \bar{x}) / s^2 - 1 \right]$$

It is also possible to estimate a and b using maximum likelihood, but the method requires an iterative procedure such as the Newton-Raphson algorithm.

Random numbers following the beta distribution can be generated in several ways. If V_1 and V_2 are independent and follow the χ^2 distribution (the section on the χ^2 distribution that follows will discuss generating random numbers following that distribution) with parameters c_1 and c_2 respectively, then $\frac{V_1}{V_1 + V_2}$ follows a beta distribution with parameters $c_1/2$ and $c_2/2$. Alternatively, if $Y_1, Y_2, \dots, Y_n$ are independent random variables following the $U(0, 1)$ (that is, the continuous uniform distribution between 0 and 1) distribution, then the s -th order statistic Y'_s follows a beta distribution with parameters s and $n - s + 1$.

The beta distribution, as described above, is often referred to as the two-parameter beta distribution. An extension of the two-parameter beta distribution is the four-parameter beta distribution whose pdf is proportional to $(x - \alpha)^{a-1} (\beta - x)^{b-1}$, where $\alpha < x < \beta$; the variable $\frac{x - \alpha}{\beta - \alpha}$ has a two-parameter beta distribution in this case.

A well-known application of the beta distribution in education can be found in Lord (1965), where the true test score was modeled using the four-parameter beta distribution. In addition, as in Patz and Junker (1999), in applications of the Markov chain Monte Carlo (MCMC) algorithm models, the prior distribution for the guessing parameter is often assumed to be the beta distribution.

Gamma distribution

The gamma distribution is used to model continuous random variables whose range is between 0 and ∞ . The pdf of the gamma distribution is given by

$$f(x; b, c) = \frac{1}{b\Gamma(c)} \left(\frac{x}{b}\right)^{c-1} e^{-\frac{x}{b}}, b \geq 0, c > 0$$

where b is called the scale parameter and c is the shape parameter. In many applications of the distribution, b is assumed to be equal to 1. The mean of the gamma distribution is bc and the variance is b^2c .

If $2c$ is an integer, then the gamma random variable is half of a χ^2 random variable with $2c$ df. If $c = 1$, then the gamma distribution becomes the exponential distribution. If V_1 and V_2 are gamma random variables, with $b = 1$ and $c = c_1$ and c_2 respectively, then $\frac{V_1}{V_1 + V_2}$ follows a beta distribution with parameters c_1 and c_2 .

By the method of moments, the estimate of b is $s^2/\bar{x}$ and that of c is $(\bar{x}/s)^2$. It is possible to estimate the parameters using the maximum likelihood method, but that requires the use of an iterative algorithm.

If c is an integer, then $-b \prod_{i=1}^c R_i$ follows a gamma distribution with parameters b and c , where the R_i 's are independent $U(0,1)$ random variables—this result can be used to generate random numbers following the gamma distribution.

The reciprocal of a gamma random variable follows a distribution called the inverse gamma distribution. In several applications of Bayesian methods to IRT models, the prior distribution for the variance parameters is often assumed to be the inverse gamma distribution. See, for example, Bradlow et al. (1999).

Cauchy distribution

The Cauchy distribution is often of mathematical interest due to the absence of any moments (Evans et al., 2000). The pdf of the distribution is given by

$$f(x; a, b) = \left\{ \pi b \left[1 + \left(\frac{x-a}{b} \right)^2 \right] \right\}^{-1}$$

and the cumulative distribution function (cdf) is given by

$$\frac{1}{2} + \frac{1}{\pi} \tan^{-1} \left(\frac{x-a}{b} \right)$$

The mode and the median of the distribution is a , but no moments exist. The Cauchy distribution is unimodal and symmetric but has tails that are much heavier than those of the normal distribution. Fig. 1 compares the pdf of the Cauchy distribution with $a = 0$ and $b = 1$ (that is a special case of the Student's t distribution with 1 df) against that of a t distribution with 4 df and the standard normal distribution. The Cauchy distribution has the heaviest tail among the three distributions.

The ratio of two independent standard normal random variables follows a Cauchy distribution with $a = 0$ and $b = 1$. A Cauchy distribution with $a = 0$ and $b = 1$ is a special case of the Student's t distribution with one degree of freedom (df).

One set of estimates of a and b are the sample median and half of the sample interquartile range, respectively. Alternatively, one can compute maximum likelihood estimates of a and b using an iterative approach.

A random number following the Cauchy distribution can be generated by generating a random number R from the $U(0,1)$ distribution and then setting $F(x) = R$, where $F(x)$ is the cdf of the distribution. The solution is given by $a + b \tan[\pi(R - 0.5)]$.

Verhagen et al. (2016) assumed, in a Bayesian analysis using item response theory (IRT) models, that the prior distribution on the item difficulty parameters is a Cauchy distribution; the reason of this choice was that they wanted a prior distribution that has a wider tail than a normal distribution.

χ^2 distribution

The χ^2 distribution is the distribution of the sum of squares of several independent normal random variables with unit variance. A χ^2 random variable with d df and non-centrality parameter $\delta \geq 0$ has the pdf

$$f(x; d, \delta) = \frac{e^{-(x+\delta)/2}}{2^{d/2}} \sum_{j=0}^{\infty} \frac{x^{d/2+j-1} \delta^j}{\Gamma(d/2+j) 2^{2j} j!}$$

If the aforementioned normal random variables have means $\mu_1, \mu_2, \dots$, then $\delta = \sum_i \mu_i^2$.

The expectation and variance of the χ^2 distribution are $d + \delta$ and $2(d + 2\delta)$ respectively. In most common applications of the χ^2 distribution, the noncentrality parameter δ is 0. The distribution is then called a central χ^2 distribution (that is the distribution of the sum of squares of several independent standard normal variables), the summation in the pdf reduces to a single term (that for $j = 0$), the mean is d , and the variance is $2d$.

If d is an integer, a central χ^2 random variable with df d can be generated by generating d standard normal random numbers and adding their squares.

Several goodness-of-fit statistics (see the article by Tendeiro on this topic in this encyclopedia) used in educational applications follow the χ^2 distribution when the model fits the data. For example, the M_2 and χ_{pf} statistics that were suggested by

Maydeu-Olivares and Joe (2005) and Sinharay (2018), respectively, for assessing the goodness-of-fit of IRT models and person fit for response-time models follow the χ^2 distribution.

F distribution

The pdf of the F distribution is given by

$$f(x; \nu, w, \delta) = k \frac{e^{-\delta/2} \nu^{\nu/2} w^{w/2} x^{\nu/2}}{B(\nu/2, w/2)(w + \nu x)^{(w+\nu)/2}}$$

where ν and w are df's and positive integers, $\delta \geq 0$ is the noncentrality parameter, and $k = 1 + \sum_{j=1}^{\infty} \left(\frac{\nu w x / 2}{w + \nu x} \right)^j \frac{(\nu + w)(\nu + w + 2)(\nu + w + 2j - 2)}{j! \nu (\nu + 2) \dots (\nu + 2j - 2)}$. Often, $\delta = 0$, in which case $k = 1$ and the F distribution is called the central F distribution.

The mean and variance of the F distribution are $\frac{w(\nu + \delta)}{\nu(w - 2)}$ and $2 \left(\frac{w}{\nu} \right)^2 \frac{(\nu + \delta)^2 + (\nu + 2\delta)(w - 2)}{(w - 2)^2(w - 4)}$, respectively.

If two independent χ^2 random variables χ_1^2 and χ_2^2 have df's ν and w , then $\frac{\chi_1^2/\nu}{\chi_2^2/w}$ has an F distribution with ν and w df. This result can be used to generate random numbers following the F -distribution.

The F distribution has often been applied in education in analysis of variance (ANOVA; see the article by King), where the ratio of the mean square of an effect and the mean square of error has a central F distribution under the null hypothesis that the effect is zero. For example, Sinharay and Lu (2008) used ANOVA to examine if the mean of a fit statistic differed over three conditions and concluded that no difference over the conditions because of values of F statistics that were not statistically significant.

Dirichlet distribution

The Dirichlet distribution is the multivariate generalization of the beta distribution. In Bayesian analyses, the Dirichlet distribution is often used as a prior distribution of the parameters of the multinomial distribution. See, for example, Novick and Jackson (1974, chapter 10-7). Consider a k -dimensional random variable $\mathbf{X} = (X_1, X_2, \dots, X_k)$ so that the X_i 's are all positive and the sum of them is 1. If $\mathbf{X}$ follows the Dirichlet distribution, its pdf is given by

$$f(x_1, x_2, \dots, x_k; c_1, \dots, c_k) = \frac{\Gamma\left(\sum_{i=1}^k c_i\right)}{\prod_{i=1}^k \Gamma(c_i)} \prod_{i=1}^k x_i^{c_i-1}$$

where c_i , $i = 1, 2, \dots, k$ are the parameters of the distribution. The marginal distribution of X_i is the beta distribution with parameters c_i and $\sum_{j=1}^k c_j - c_i$. This property can be used to estimate the parameters c_i using the method of moments as discussed earlier for the beta distribution. For $k = 2$, the Dirichlet distribution becomes the beta distribution with parameters c_1 and c_2 .

To generate a random number $\mathbf{x} = (x_1, x_2, \dots, x_k)$ from the Dirichlet distribution with c_i s as parameters, one can generate a sequence of independent draws y_i , $i = 1, 2, \dots, k$, where y_i is a draw from the gamma distribution (to be discussed later) with parameters $b = 1$ and $c = c_i$, and compute $x_i = \frac{y_i}{\sum_{j=1}^k y_j}$, $i = 1, 2, \dots, k$

van Duijn and Jansen (1995) modeled spelling errors made by 721 school students on 4 dictation tests each of which includes 20 Dutch words. They assumed that the number of errors made by a student on a test follows a Poisson distribution (see the article on discrete distributions by Sinharay in this encyclopedia) where the mean parameter of the distribution is a product of an examinee ability parameter and a difficulty parameter specific to that examinee-test combination. The difficulty parameters are assumed to sum to 1 for each examinee over the four tests and are assumed to follow a Dirichlet distribution whose parameters are to be estimated. In an analysis of mathematics assessment data from early childhood longitudinal study using latent classes, Depaoli et al. (2016) assumed a Dirichlet prior distribution on the proportion of examinees belonging to each latent class.

Wishart distribution

The Wishart distribution is the multivariate generalization of the χ^2 distribution and is the distribution of a scalar multiple of the maximum-likelihood estimator of the covariance matrix of a multivariate normal distribution. A k -dimensional random variable $\mathbf{X}$ following the Wishart distribution has a pdf equal to

$$|\mathbf{X}|^{\frac{n-k-1}{2}} e^{-\frac{1}{2}\text{tr}(\Sigma^{-1}\mathbf{X})}$$

$$\frac{2^{nk/2} \pi^{k(k-1)/4} |\Sigma|^{n/2}}{\prod_{i=1}^k \Gamma\left(\frac{n+1-i}{2}\right)}$$

where Σ is a $k \times k$ matrix, n is the df, $\text{tr}(A)$ is the trace of matrix A and $|A|$ is the determinant of the matrix A . The distribution has a mean of $n\Sigma$.

If $Y_1, Y_2, \dots, Y_n$ are k -dimensional random numbers independently drawn from a multivariate normal distribution with mean $\mathbf{0}$, where $\mathbf{0}$ denotes a vector of zeroes, and variance matrix Σ , then the distribution of $\sum_{i=1}^n Y_i Y_i'$ is a k -dimensional Wishart distribution with k df and parameter Σ . This result can be used to generate random matrices following the Wishart distribution.

The inverse of a random variable following a Wishart distribution follows the *inverse Wishart distribution*. The inverse Wishart distribution is often assumed to be the prior distribution on the variance matrix in a Bayesian approach to IRT modeling (e.g., [Johnson and Sinharay, 2005](#)).

Conclusions

Among the numerous continuous statistical distributions, this article provides a brief overview of a few distributions that have found applications in the field of education. [Table 1](#) shows the pdf, mean, and variance of all the distributions discussed in this article (for simplicity, the table includes the expression of the variance of only one element/component for the Dirichlet and Wishart distributions). See, for example, [Evans et al. \(2000\)](#), ([Johnson et al. 1994, 1995](#)), [Kotz et al. \(2000\)](#) for more detailed descriptions of these and many more continuous distributions.

Several continuous distributions (such as the beta, gamma, exponential, and normal distributions) belong to the *exponential family of distributions* (e.g., [Haberman, 2016](#)) that have pdf of the form

$$\exp \left[\sum_i A_i(\theta) B_i(x) + C(x) + D(\theta) \right]$$

Table 1 Some features of the continuous distributions discussed in this article.

Distribution	Pdf	Mean	Variance
Uniform	$\frac{1}{b-a}$	$\frac{a+b}{2}$	$\frac{(b-a)^2}{12}$
Exponential	$\frac{1}{b} e^{-x/b}$	b	b^2
Normal	$\frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{(x-\mu)^2}{2\sigma^2}}$	μ	σ^2
Lognormal	$\frac{1}{x\sigma\sqrt{2\pi}} e^{-\frac{1}{2}\left(\frac{\log(x)-\mu}{\sigma}\right)^2}$	$e^{\mu+\frac{\sigma^2}{2}}$	$e^{2\mu+\sigma^2}(e^{\sigma^2}-1)$
Student's t	$\frac{\frac{1}{\Gamma(\nu/2)} \frac{v^{\nu/2} e^{-v/2}}{\pi^{0.5} (v+x^2)^{(\nu+1)/2}} \sum_{i=0}^{\infty} \Gamma\left(\frac{\nu+i+1}{2}\right) \frac{(x\delta)^i}{i!} \left(\frac{2}{v+x^2}\right)^{i/2}}$	$\frac{\delta(v/2)^{1/2} \Gamma((\nu-1)/2)}{\Gamma(\nu/2)}$	$\frac{v}{v-2} (1 + \delta^2) - \frac{v\delta^2}{2} \left(\frac{\Gamma((\nu-1)/2)}{\Gamma(\nu/2)} \right)^2$
Beta	$\frac{1}{B(a,b)} x^{a-1} (1-x)^{b-1}$	$\frac{a}{a+b}$	$\frac{ab}{(a+b)^2(a+b+1)}$
Gamma	$\frac{1}{b\Gamma(c)} \left(\frac{x}{b}\right)^{c-1} e^{-\frac{x}{b}}$	bc	b^2c
Cauchy	$\left\{ \pi b \left[1 + \left(\frac{x-a}{b} \right)^2 \right] \right\}^{-1}$	Does not exist	Does not exist
χ^2	$\frac{e^{-(x+\delta)/2}}{2^{d/2}} \sum_{j=0}^{\infty} \frac{x^{d/2+j-1} \delta^j}{\Gamma(d/2+j) 2^{2j} j!}$	$d + \delta$	$2(d + 2\delta)$
F	$k \frac{e^{-\delta/2} v^{v/2} w^{w/2} x^{(v-2)/2}}{B(v/2, w/2) (w+vx)^{(v+w)/2}}$	$\frac{w(v+\delta)}{v(w-2)}$	$2\left(\frac{w}{v}\right)^2 \times \frac{(v+\delta)^2 + (v+2\delta)(w-2)}{(w-2)^2(w-4)}$
Dirichlet	$\frac{\Gamma\left(\sum_{i=1}^k c_i\right)}{\prod_{i=1}^k \Gamma(c_i)} \prod_{i=1}^k x_i^{c_i-1}$	$E(x_i) = \frac{c_i}{\sum_{i=1}^k c_i}$	$V(x_i) = \frac{c_i \left(\sum_{i=1}^k c_i - c_i \right)}{\left(\sum_{i=1}^k c_i \right)^2 \left(\sum_{i=1}^k c_i + 1 \right)}$
Wishart	$ x ^{\frac{n-k-1}{2}} e^{-\frac{1}{2} \text{tr}(\Sigma^{-1}x)}$ $2^{nk/2} \pi^{k(k-1)/4} \Sigma ^{1/2} \prod_{i=1}^k \Gamma\left(\frac{n+1-i}{2}\right)$	$n\Sigma$	$V(x_{ij}) = 2n\sigma_{ij}^2$

where $\theta = (\theta_1, \theta_2, \dots, \theta_p)$ is the p -dimensional parameter vector of the distribution. Uniform and Cauchy distributions are examples of distributions that do not belong to the exponential family. The exponential family of distributions have several attractive properties, such as the set of $B_i(x)$'s being jointly sufficient for the parameters θ . Hence, the family has been applied to several applications in education. See, for example, [Haberman \(2008\)](#), for an application of the family of distributions to equating.

The choice of the specific continuous distribution to be used in a specific application depends on several issues. If a specific distribution is used in practice for data of the type an investigator has that distribution should be the first choice. For example, a Dirichlet distribution is often applied in practice to model the probabilities from a multinomial distribution. If such knowledge is lacking, a sensible approach is to graphically plot the data and try to find a distribution that is expected to describe the data adequately. After fitting a distribution to a data set, methods of goodness-of-fit can be used to examine whether the distribution provides an adequate description of the data set.

A discrete random variable (denoted X) is one that can take one of an enumerable or countably infinite set of values x_i , $i = 1, 2, \dots$, each with a specific probability p_i so that the probabilities over all the values add up to 1 (that is, $\sum_i p_i = 1$). The function that specifies the probabilities for the possible values is defined as the probability mass function (pmf). The cumulative distribution function (cdf) of a discrete distribution, which provides the probability that the corresponding random variable is smaller than or equal to a specific value, is a step function. Discrete random variables occur naturally in statistics and several other fields including education; for example, the number of items correctly answered on a test, the number of examinees passing a test etc. constitute discrete random variables. [Holland \(1979\)](#) commented that the world is full of discrete data. Hence several types of discrete random variables have been suggested in the literature. There also exist several statistical methods specifically designed to handle discrete data—see, for example, [Bishop et al. \(1975\)](#) and the article by Anderson on categorical data analysis in this encyclopedia.

In the following sections, several discrete distributions are discussed. For each distribution, its genesis, pmf, moments, estimation of the moments, methods to generate values of a random variable following that distribution, and relationships to other distributions (if any) are discussed. Applications of these distribution to educational problems are also mentioned, when appropriate.

Bernoulli distribution

The Bernoulli distribution is the most basic discrete distribution. A variable that follows the distribution can take one of two possible values, 1 (usually referred to as a success) or 0 (a failure), where the probability of success is p , $0 \leq p \leq 1$. An example of a Bernoulli random variable (that is, a variable that follows the Bernoulli distribution) is the outcome of a coin toss, where the outcome is either a head (success) or a tail (failure) and the probability of a head is a number between 0 and 1 (the probability is 0.5 if the coin is balanced).

The pmf of a Bernoulli distribution is given by

$$P(X=x) = p^x(1-p)^{1-x}$$

where x can be either 0 or 1. The cdf $F(x)$ of the distribution is 0 if $x < 0$, $1-p$ if $0 \leq x < 1$, and 1 if $x \geq 1$. The mean and the variance of the distribution are p and $p(1-p)$.

The maximum likelihood estimate (MLE) of p from a sample $x_1, x_2, \dots, x_s$ from the Bernoulli random variable is the sample mean $\bar{x} = \frac{1}{s} \sum_{i=1}^s x_i$, which is the proportion of successes in the sample. For example, six heads in 10 coin tosses results in the sample mean and hence the MLE of p being equal to 0.6.

To generate a random number X from the Bernoulli distribution, one has to first generate a random number R from the $U(0, 1)$ distribution, that is, the uniform distribution between 0 and 1 (A review of the uniform distribution can be found in the article by Sinharay on continuous distributions in this encyclopedia). If R is less than p , then X is set to 0; otherwise, X is set to 1.

The Bernoulli distribution is employed in the basic building block of item response theory (IRT) models (see, for example, articles by Ackerman et al. and Cai in this encyclopedia, and [Hambleton and Swaminathan, 1985](#)), which are heavily used to analyze data from educational tests. Several educational tests include dichotomously scored (0/1) items. In an application of an IRT model, these item scores are assumed to follow the Bernoulli distribution with p equal to a suitably chosen nonlinear function of the examinee and item characteristics.

Binomial distribution

If $Y_1, Y_2, \dots, Y_n$ are independent Bernoulli random variables, all with success probability $p, 0 \leq p \leq 1$, then $\sum_{i=1}^n Y_i$, which denotes the number of successes among the Y_i s, is a binomial random variable with number of trials = n and success probability p .

The pmf of a Binomial distribution is given by

$$P(X=x) = \binom{n}{x} p^x (1-p)^{n-x}, x = 0, 1, 2, \dots, n$$

The mean and variance of the distribution are np and $np(1-p)$.

The MLE of p from a sample $x_1, x_2, \dots, x_n$ from the Binomial distribution with n trials and success probability p is the ratio of the sample mean $\bar{x}$ and n . To generate a random number from a binomial distribution, one can generate n Bernoulli random variables, all with probability p , and add them up. Alternatively, one can compute the cdf of the binomial distribution, generate $R \sim U(0, 1)$, and then take x as the random number from the binomial distribution if the cdf for $x-1$ is less than R and the cdf for x is greater than or equal to R (this is often called the *cdf-inversion* method).

Several applications of the binomial distribution to educational data can be found in [Novick and Jackson \(1974\)](#). In one such application, the number of words spelled correctly (out of a total of n words) by a student, where each word is equally difficult to spell, is assumed to follow the binomial distribution. The binomial distribution has also played a major role in the modeling of raw scores on educational tests. For example, [Keats and Lord \(1962\)](#) denoted the true proportion-correct score (or relative true score) and observed raw score on a test with I dichotomously scored items of a randomly chosen examinee as p and X , respectively. The distribution of X given p was assumed to be the binomial distribution with I trials and success probability p . If $f(p)$ denotes the population distribution of the true proportion-correct score, then the marginal distribution of X is given by

$$P(X=x) = \int_p \binom{I}{x} p^x (1-p)^{I-x} f(p) dp$$

The discrete distribution provided by the above equation is referred to as the *beta-binomial distribution*, which is another, albeit less popular, discrete distribution.

Geometric distribution

If a sequence of independent Bernoulli random variables are generated with the same success probability $p, 0 < p \leq 1$, the number of trials or failures before the first success follows a geometric distribution.

The pmf of a variable X following the geometric distribution is given by

$$P(X=x) = p(1-p)^x, x = 0, 1, 2, \dots, \infty$$

Thus, the number of possible values of a geometric random variable is countably infinite.

The mean and variance of a geometric distribution are $\frac{1-p}{p}$ and $\frac{1-p}{p^2}$. The maximum likelihood estimate of p from a sample from the geometric distribution is $\frac{1}{1+\bar{x}}$.

The cdf of the geometric distribution for an integer r is given by $P(X \leq r) = 1 - (1-p)^{r+1}$. Using this expression, a random number from a geometric distribution can be generated by first generating $R \sim U(0, 1)$ and then computing the integer part of $\frac{\log(R)}{\log(1-p)}$.

In an approach to control item exposure in computerized adaptive tests (CATs) suggested by [Lewis \(2007\)](#), one assigns each item in the item pool a probability r of actually being administered given that it has been selected by the CAT algorithm used to deliver the test. Suppose that at each stage of the CAT, the algorithm gives an ordered list of the remaining items in the item pool in terms of attractiveness to be administered. The first item in the list would have a probability r of being administered at this stage. The second item has a probability $r(1-r)$ of being administered, the third a probability of $r(1-r)^2$ and so on. In general, if G denotes the random position in the list of the item that is actually administered at this stage, then G follows the geometric distribution.

Hypergeometric distribution

Suppose that a sample of n items was drawn without replacement from a population of N elements of which M elements have a certain attribute. The number of elements in the sample with the attribute is a hypergeometric random variable. This distribution could arise when, for example, a group of N examinees includes M examinees who passed a test and $(N-M)$ who failed; if one draws a sample of n examinees from the group, the variable denoting the number of examinees who passed in the sample, X , is a hypergeometric random variable. The parameters for the distribution are N and M .

The pmf of the distribution is given by

$$P(X=x) = \frac{\binom{M}{x} \binom{N-M}{n-x}}{\binom{N}{n}}$$

The mean and variance of the distribution are $\frac{nM}{N}$ and $\frac{(nM/N)(1-M/N)(N-n)}{N-1}$, respectively.

When $\frac{n}{N}$ is small and N is large, the hypergeometric distribution can be approximated by a binomial random variable with n trials and $p = \frac{M}{N}$.

The parameters of the distribution can be estimated from a sample of size n using the MLE. The estimate of N is the largest integer less than or equal to $\frac{nM}{x}$ and that of M is the largest integer less than or equal to $\frac{(N+1)x}{n}$.

To draw a random number from the distribution, one can construct a routine that simulates an experiment, by drawing elements at random, that will generate a hypergeometric random variable. For example, for given values of N (the number of examinees), M (the number of examinees who passed), and n (the number of draws), one can draw n elements from a sample of N examinees among whom M have been marked as “passed”; the number of examinees marked as “passed” in the sample of n would be a random draw from the hypergeometric distribution. Alternatively, one can compute the cdf of the distribution and then generate a hypergeometric random number with the help of a single $U(0, 1)$ random number and the cdf-inversion method.

Meijer (2004) suggested a nonparametric approach to assess person fit. In the approach, one considers a pair of subtests, one easier and the other more difficult, and then examines whether the number correct score on the more difficult subtest (x_D) is exceptionally low given the number correct score on the two subtests combined (x_T). Suppose I_T denotes the number of items in the two subtests combined and I_D denotes the number of items on the more difficult subtest. To perform the examination, one computes the probability of an exceptionally low subtest score under the assumption of the hypergeometric distribution, with I_T , I_D , and x_T playing the roles of N , M and n , respectively.

Negative binomial distribution

The number of failures before the n -th success in a sequence of draws of Bernoulli random variables, where the success probability is p in each draw, is a negative binomial random variable. The pmf of the distribution is given by

$$P(X=x) = \binom{n+x-1}{n-1} p^n (1-p)^x, 0 < p \leq 1$$

If X follows the negative binomial distribution with n successes and success probability of p , then X is also the distribution of the sum of n independent geometric random variables with success probability of p .

The mean and variance of a negative binomial distribution are $n \frac{1-p}{p}$ and $n \frac{1-p}{p^2}$.

The MLE of p from a sample from the negative binomial distribution is $\frac{n}{n+\bar{x}}$, where $\bar{x}$ is the sample mean.

If p is small, one can generate a negative binomial random number by adding up n geometric random numbers. Another way is to generate a sequence of $U(0, 1)$ random variable values. When the number of those values less than p first reaches n , the number of values that are greater than p is a draw from the negative binomial distribution. Oliveira et al. (2018) used the negative binomial to model data on the number of allocated students for several combinations of institution and program under the Portuguese higher education system.

Poisson distribution

The Poisson distribution describes the probability of finding exactly x events in a given length of time if the events occur independently at a constant rate. In addition, the Poisson distribution can be obtained as an approximation of a binomial distribution when the number of trials n of the latter distribution is large, success probability p is small, and np is a finite number.

The pmf of the Poisson distribution is given by

$$P(X=x) = \frac{e^{-\lambda} \lambda^x}{x!}, x = 0, 1, \dots, \infty$$

where λ is a positive number. Both the mean and variance of the Poisson distribution are equal to λ .

The MLE of λ from a sample from the Poisson distribution is the sample mean.

It is possible to generate a Poisson random variable by generating a random number following the $U(0, 1)$ distribution and then using the cdf-inversion method.

The Poisson distribution has been applied in education, for example, by Novick (1969), for modeling the number of errors committed by an examinee while reading a text—the λ parameter was assumed to be a product of a text difficulty parameter for the corresponding text and an error propensity parameter for the corresponding examinee.

An extension of the Poisson distribution is the zero-inflated Poisson (ZIP) distribution that is used for data that include an excessive number of individuals with a zero value of the variable of interest. The pmf of the ZIP distribution is given by

$$P(X=x) = \begin{cases} \rho + (1-\rho)e^{-\lambda} & \text{if } x = 0 \\ (1-\rho) \frac{e^{-\lambda} \lambda^x}{x!} & \text{if } x > 0 \end{cases}$$

where the parameter ρ is included to account for the extra zero values. A closely related model is the hurdle Poisson distribution whose pmf is given by

$$P(X=x) = \begin{cases} \rho & \text{if } x = 0 \\ \frac{1-\rho}{1-e^{-\lambda}} \frac{e^{-\lambda} \lambda^x}{x!} & \text{if } x > 0 \end{cases}$$

Salehi and Roudbari (2015) used the ZIP distribution to model the number of failed courses and semesters for the students of a university in Iran and Desjardins (2016) used the ZIP distribution to model data on the number of days suspended for students from a large urban school district.

The multinomial distribution

The multinomial distribution is a multivariate generalization of the binomial distribution. Consider a trial that results in exactly one of some fixed finite number k of possible outcomes, with probabilities $p_1, p_2, \dots, p_k$ (so that $p_i \geq 0$ for $i = 1, \dots, k$ and $\sum_{i=1}^k p_i = 1$), and there are n independent trials. Then let the random variables X_i indicate the number of times outcome number i was observed over the n trials. Then $X = (X_1, X_2, \dots, X_k)$ follows a multinomial distribution with parameters n and $\mathbf{p}$, where $\mathbf{p} = (p_1, p_2, \dots, p_k)$. Note that if X_i has the value x_i , $i = 1, \dots, k$, for a sample, then $\sum_{i=1}^k x_i = n$. An example where a multinomial random variable could occur is during the throw of a die. Let $X_i, i = 1, 2, \dots, 6$, denote the number of times i is observed in n throws of a die. Then $X = (X_1, X_2, \dots, X_6)$ has a multinomial distribution and $\sum_{i=1}^6 x_i = n$. If the die is fair, then $p_i = \frac{1}{6}$ for all i .

The pmf of the multinomial distribution is given by

$$P(X_1 = x_1, X_2 = x_2, \dots, X_k = x_k) = \frac{n!}{x_1! x_2! \dots x_k!} p_1^{x_1} p_2^{x_2} \dots p_k^{x_k}$$

where $\sum_{i=1}^k x_i = n$. If $k = 2$, the multinomial distribution becomes a binomial distribution with n trials and success probability p_1 . When $X = (X_1, X_2, \dots, X_k)$ follows a multinomial distribution with the pmf given above, X_i follows a binomial distribution with n trials and success probability p_i . Hence, the mean and variance of X_i are np_i and $np_i(1 - p_i)$, respectively. The covariance between X_i and X_j is $-np_i p_j$.

The MLE of p_i for a multinomial distribution is the ratio of the sample mean of x_i 's and n .

The straightforward way to generate a multinomial random variable is to simulate an experiment (by drawing n uniform random numbers that are assigned to specific bins according to the cumulative value of the $\mathbf{p}$ vector) that will generate a multinomial random variable.

The multinomial distribution has been applied to build statistical models for the number of examinees who obtained various raw scores on a test (e.g., Holland and Thayer, 2000) and for the number of examinees who obtained specific patterns of scores such as $\{0, 1, 1, 0, 1, 0, 0, \dots, 1\}$ on the items of a test (e.g., Holland, 1990).

Conclusions

Among the numerous discrete probability distributions, this article provides a brief overview of arguably the most popular seven such distributions, all of which have found applications in education. Table 1 shows the pmf, mean, and variance of all the distributions discussed in this article. See, for example, Evans et al. (2000), Johnson et al. (2005, 1997) for more details on these and many more discrete distributions. The choice of the specific distribution to be used in a specific application depends on several issues. If a specific distribution is used in practice for data of the type an investigator has, that distribution should be the first choice. If such knowledge is lacking, a sensible approach is to graphically plot the data and try to find a distribution that is expected to describe the data adequately. After fitting a distribution to a data set, methods of goodness-of-fit (see the article by Ames Boykin et al. in this encyclopedia) can be used to examine whether the distribution provides an adequate description of the data set.

Table 1 Some features of the discrete distributions discussed in this article.

Distribution	pmf	Mean	Variance
Bernoulli	$p^x(1-p)^{1-x}$	p	$p(1-p)$
Binomial	$\binom{n}{x} p^x(1-p)^{n-x}$	np	$np(1-p)$
Geometric	$p(1-p)^x$	$\frac{1-p}{p}$	$\frac{1-p}{p^2}$
Hypergeometric	$\frac{\binom{M}{x} \binom{N-M}{n-x}}{\binom{N}{n}}$	$\frac{nM}{N}$	$\frac{(nM/N)(1-M/N)(N-n)}{N-1}$
Negative binomial	$\binom{n+x-1}{n-1} p^n(1-p)^x$	$n \frac{1-p}{p}$	$n \frac{1-p}{p^2}$
Poisson	$\frac{e^{-\lambda} \lambda^x}{x!}$	λ	λ
Multinomial	$\frac{n!}{x_1! x_2! \dots x_k!} p_1^{x_1} p_2^{x_2} \dots p_k^{x_k}$	np_i	$np_i(1-p_i)$

Introduction

The aim of descriptive statistics is to summarize categorical and numerical data in an informative way, both numerically and graphically. Descriptive statistics are used to help describe key features or characteristics of data, such as the shape of their distribution, where the center lies, and how the data vary about that center. Ideally, a collection of descriptive statistics is chosen to convey the data's salient features in a more concise, but just as effective, manner as reporting each individual value.

Descriptive statistics form a basis for all quantitative analysis and are a precursor for inferential statistics, which uses properties of a data set to make inference and predictions beyond the data. Depending on the scope of a project, descriptive statistics alone may be sufficient, or they can be used to inform further statistical analyses. In this entry, we provide an overview of commonly used descriptive statistics and how they are interpreted in summaries and analyses.

Descriptive statistics begin with a data set consisting of a set of variables with values or observations for each observational unit. We call the set of all observational units of interest the *population*, and any numerical descriptor of the population is called a *parameter*. In most analyses it is difficult to collect data for the entire population and thus the data set will only contain information about a subset of the population of interest. We call this subset of the population a *sample*, and any numerical descriptor of a sample is called a *statistic*. For example, suppose our population of interest is all high school students at a particular school, and consider a set of data on high school students that records the name, gender identity, year in school (9th, 10th, 11th, 12th), grade point average (GPA), and Scholastic Aptitude Test (SAT) score of each student. If our data set contains observations for every student in the school, then the set contains the entire population. If our data set instead contains only a subset of students in the school, we would call this set a sample. In this example, each student is an observational unit or case, and name, gender identity, year, GPA, and SAT score are variables.

In the following sections, we focus on statistics that describe *univariate data*, that is, data on a single variable, and we divide variables into two types: categorical and numerical. The variable type determines which types of descriptive statistics we can use and the types of analyses we can perform. We first discuss numerical and graphical methods to describe categorical variables, such as frequency tables and bar charts. For describing numerical data, we discuss commonly used measures of center, such as mean and median; commonly used measures of variability, such as standard deviation and interquartile range; commonly used measures of shape, such as skew and kurtosis; and commonly used measures of location, such as percentiles and standardized scores. We conclude by briefly discussing methods, such as a scatterplot and correlation, used to summarize bivariate numerical data and then present a practical example of how many of these descriptive statistics may be used and interpreted in an educational context.

Describing univariate categorical data

Many data sets contain *categorical variables* whose possible values are categories or levels of an attribute, allowing us to compare the frequency or percentage of observations in each category. For instance, in our previous example, gender identity and year are

Fig. 1 Frequency table (left) and bar chart (right) of students' year in high school.

categorical variables that each have distinct categories. When the categories have a natural ordering, such as 9th, 10th, 11th, and 12th grade for year, we call the variable an ordinal categorical variable and report the categories in their natural order. When the categories have no such ordering, such as male, female, non-binary, etc. for gender identity, we call the variable a nominal categorical variable and can report the categories in any order.

To summarize categorical variables, counts or frequencies of observations in each category, as well as relative frequencies, can be displayed numerically and visually. The relative frequency or proportion of observations in a particular category is calculated by dividing the number of observations in the category by the total number of observations in the sample. Numerically, these descriptive statistics can be displayed using a frequency table that presents the name, frequency, and relative frequency of each category. These statistics can also be displayed and examined visually using bar charts, where vertical bars are drawn for each category according to their frequency or relative frequency. To demonstrate each of these methods, [Fig. 1](#) provides a frequency table and a bar chart for the nominal categorical variable year for a fictional high school. We can interpret these summaries using statements such as, "In the data set, the year with the most students is 11th grade with 372 students" or "Approximately 25.42% of the students in the data set are in 9th grade." In this way, we can summarize the data for a categorical variable more succinctly than listing all the observations.

Describing univariate numerical data

Numerical variables are variables whose values are represented on a numeric or quantitative scale, like GPA and SAT score in our initial example. When summarizing numerical variables, we seek to describe properties of the data distribution, that is, to describe information about the values observed and the overall pattern of how often the possible values occur. The simplest way to examine the distribution for a given variable is through graphical methods, such as histograms or box plots. Here, we focus on numerical summaries used to describe key features of a single variable's distribution—its center, variability, and shape—as well as measures of location, such as percentiles and standardized scores, that describe how an individual observation relates to the variable's distribution.

Measures of center

One salient feature of data is the center of its distribution, or the typical value of a numeric variable. Most commonly, the mean and the median are calculated, but other methods are sometimes useful. Choosing which measure(s) of center to report requires an understanding of the context of the question to be answered and the meaning behind the data, as well as consideration of the presence of extreme values and the overall shape of the distribution. Each measure of center tells us something different about the data, and each is impacted differently by the presence of extreme values. In this entry, we focus on the mean and median.

The *mean* is the arithmetic average, calculated by adding all data values together and dividing by the count or the total number of values. It tells us the fair-share value, the value at which the total would be unchanged if each observation were equal. The mean is also the balancing point where the total distance each observation lies from the mean is balanced or equal on each side. The *median* represents the middle value, separating the top and bottom 50% of the ordered observations. To find the median, the data are ordered from least to greatest, and a value that splits the observations into two subsets of equal size is identified. If there are an odd number of observations, the median is the value of the single observation that lies in the middle of the ordered data, but if there are an even number of observations, the median is typically the mean of the two observations that lie in the middle. For example, the median of the values 1, 3, and 5 would be 3, whereas the median of the values 1, 3, 5, and 10 would be $(3 + 5)/2$.

$2 = 4$. In this way, the median tells us the middle of the data, with approximately half above and half below and with little regard to the magnitude of each observation.

We often consider the presence of extreme values when deciding which measure(s) of center to report. The mean gives equal weight to all data values, so values that are extremely small or large relative to the other values have large impact on the value of the mean. In contrast, the median relies on the relative ordering rather than the magnitude of the data values, so extreme values have little or no impact. This resistance to extreme values makes the median useful when describing data with relatively extreme observations or outliers.

The context of the data is also important to consider when reporting a measure of center. The mean and the median offer different information, and we must often decide whether to report the mean or the median, or both. For example, when examining the values of properties in a school's area of service, the median value would let us know that approximately half the properties are worth less and approximately half are worth more. This could tell us something about the typical financial situation of families in the area, and would not change much if a new family moved in and bought a relatively expensive property. On the other hand, the mean, which gives equal weight to each observation, would be influenced by such a relatively expensive property value, resulting in a value that may not represent what is typical for the area. The mean tells us the value of a property if they were all worth the same and can better represent the typical value in the absence of extreme values. Because each measure of center conveys different information, it is important to understand how the statistic will be used when deciding which to report.

Measures of variability

A measure of center or typical value of a numeric variable only describes a portion of the overall data distribution. For a more complete description of the distribution, we also need to summarize the amount of variability in the data. For example, Fig. 2 illustrates midterm exam scores for two different classes that have the same mean midterm exam score of 70 points, but noticeably different distributions; the way the scores vary from one another differs from class to class. This variation is illustrated by the horizontal spread of the data.

Variability can be measured in multiple ways. The most simple measure of variability is *range*, calculated by the difference in the maximum and minimum values of a variable:

$$\text{Range} = \text{Maximum value} - \text{Minimum value}.$$

However, this measure does not utilize all the information contained in the data, so other measures of variability, such as standard deviation and interquartile range, are typically presented.

Standard deviation

A common measure of variability or spread, *standard deviation*, provides a typical distance of how far the observations are from the mean. This measure helps us understand whether most observations are close to the mean or far from it. The sample standard deviation, s , is calculated using the formula:

$$s = \sqrt{\frac{\sum_{i=1}^n (x_i - \bar{x})^2}{n - 1}}$$

where $\bar{x}$ is the sample mean. Note that we divide by the degrees of freedom, $n - 1$, versus the complete sample size, n , so that the *sample variance*, s^2 , is an unbiased estimate of the population variance, σ^2 . If the entire set of N population values and their mean μ are known, then the population variance, σ^2 , is calculated based on the formula for the population standard deviation, σ :

Fig. 2 Dot plots of students' midterm exam scores for two different classes. Plots were made using "Explore Quantitative Data" from "The Art and Science of Learning From Data Web Apps" <https://artofstat.com/web-apps>.

$$\sigma = \sqrt{\frac{\sum_{i=1}^n (x_i - \mu)^2}{N}}$$

Standard deviation conveniently measures the typical distance of an observation from the mean in the data's original units. However, this measure of variability, like the mean, is affected by extreme observations and is most appropriate for a roughly symmetric distribution (see [Skewness](#) section). Sample variance, s^2 , which is the square of standard deviation, is similarly affected by extreme observations but not as easily interpreted because it is measured in squared units.

Interquartile range

The *interquartile range* (IQR) can be used in lieu of, or in addition to, standard deviation to measure variability. Similar to the median, the IQR is resistant to extreme observations or outliers, because it depends on the order rather than the numeric values of the observations. The IQR represents the distance between the top 25% of the observations and the bottom 25% of the observations. That is, the IQR is the range of the middle 50% of the observations. Formally, IQR is calculated as the difference between the third quartile value, Q_3 , (75th percentile) and the first quartile value, Q_1 , (25th percentile):

$$IQR = Q_3 - Q_1$$

where the first quartile is calculated as the median of the sorted observations below the median and the third quartile is calculated as the median of the sorted observations above the median. Thus, the values of Q_1 , the median, and Q_3 split the data into approximately fourths. These three measures coupled with the minimum and maximum values form the *5 number summary*.

The IQR is often displayed in a box plot, where the size of the box is proportional to the IQR, visually displaying a measure of the variability in the data. [Fig. 3](#) displays box plots of the same two classes' exam scores presented in [Fig. 2](#), where Class 1 has less variability than Class 2. Here, the length of the box for Class 1 is visibly smaller than that of Class 2.

Reporting measures of variability

Within reports and statistical software output, tables are often used to summarize measures of center and variability, as well as other descriptive statistics. An example is given for the midterm exams in [Table 1](#). We see from these summary statistics that in Class 1, the middle 50% of students scored between 65 and 74.4 points, whereas the Class 2 scores were much more spread out, with the middle 50% between 58 and 82 points. This observation is supported by Class 2 having a standard deviation more than twice as large as Class 1, meaning that Class 2 scores are, in general, more than twice as far from their mean as scores from Class 1. By examining the descriptive statistics presented in the table, we can succinctly characterize and understand the center and variability of the data distribution.

Fig. 3 Box plots of students' midterm exam scores for two different classes. Plots were made using "Explore Quantitative Data" from "The Art and Science of Learning From Data Web Apps" <https://artofstat.com/web-apps>.

Table 1 Descriptive statistics of the students' midterm exam scores displayed in [Figs. 2 and 3](#) for each class.

Class	n	Mean	Standard deviation	Minimum	Q_1	Median	Q_3	Maximum	IQR
Class 1	30	70.0	6.77	58.0	65.0	69.8	74.4	84.7	9.4
Class 2	30	70.0	14.83	41.0	58.0	71.5	82.0	98.0	24.0

Measures of shape

When summarizing data, we want to consider multiple characteristics of a distribution, not just its center and variability. Considering additional characteristics, such as a data distribution's shape, offers useful information that measures of center and variability may not provide, such as how the data are distributed across the range of values. Graphical displays and plots help depict these characteristics by illustrating not only the center and variability of a data distribution, but also its shape or overall pattern. For example, the plots in Fig. 4 display the midterm exam scores for two different classes of 30 students that each have the same mean of 75.2 points and the same standard deviation of 10 points, as reported in Table 2. However, the two distributions of exam scores are not identical. Even though Class 1 and Class 2 have the same mean score and the same standard deviation, the plots illustrate how each set of exam scores is distributed differently over the range of values from 49 to 89 points. For instance, the dot plots show that Class 1's midterm exam scores are primarily concentrated around two different values or modes, 70 points and 84 points, creating a bimodal distribution, whereas Class 2's midterm exam scores are primarily concentrated around 80 points, creating a unimodal distribution.

By displaying data visually, we are able to notice and compare aspects of each distribution's shape, such as its modality, that the mean and standard deviation do not convey. Other aspects we may notice about a data distribution's shape include skewness and kurtosis. Although numerical measures of skewness and kurtosis are not typically reported in educational research, these various aspects of a data distribution's shape, as well as its center and variability, allow us to more holistically describe and understand key features of the data. In the following sections, we discuss each of these distributional characteristics, summarizing what each represents and how to interpret statistical measures of skewness and kurtosis for unimodal distributions.

Skewness

Skewness is a distributional characteristic we use to help describe the lack of symmetry in a data distribution. Graphically, we can visualize a data distribution's symmetry, or lack thereof. When a distribution of values is approximately symmetric, such as those

Fig. 4 Dot plots (top panel) and box plots (bottom panel) of students' midterm exam scores for two different classes. Plots were made using "Explore Quantitative Data" from "The Art and Science of Learning From Data Web Apps" <https://artofstat.com/web-apps>.

Table 2 Descriptive statistics of the students' midterm exam scores displayed in Fig. 4 for each class.

Class	<i>n</i>	Mean	Standard deviation	Minimum	Q1	Median	Q3	Maximum	IQR	Skew
Class 1	30	75.2	10.00	49.0	70.0	75.0	84.0	89.0	14.0	−0.85
Class 2	30	75.2	10.00	49.0	74.0	78.5	81.0	89.0	7.0	−1.33

Fig. 5 Histograms of approximately symmetric distributions, one that is unimodal and bell-shaped like a Normal distribution (left) and one whose frequencies are nearly uniform across the range of scores (right).

shown in **Fig. 5**, the mean is close to the median and each side of the distribution along the mean or median is roughly a mirror image of itself. However, when one side, or tail, of a distribution stretches further from the center than the other tail, this asymmetry is called skew. For example, the two distributions of midterm exam scores displayed by the dot plots in **Fig. 4** are asymmetric or skewed, because they both have observations that extend or stretch their lower tails further to the left than their upper tails extend to the right. The boxplots also visually depict this negative or left skew by showing how the distance between the minimum score and the median is greater than the distance between the median and the maximum score for each class's distribution of midterm exam scores. Based on these characteristics, Class 1's distribution of midterm exam scores can be described as a left-skewed bimodal distribution, and Class 2's as a left-skewed unimodal distribution.

In general, a unimodal distribution's skew or lack of symmetry is described by the direction in which one of its tails stretches further from the mean or median than its other tail. A left- or negative-skewed unimodal distribution has a lower tail that creates an asymmetry in the distribution by extending far to the left, as illustrated by the plots of Class 2's midterm exam scores in **Fig. 4**, whereas a right- or positively-skewed unimodal distribution's upper tail extends far to the right, as illustrated in **Fig. 6**. Numerically, the skew of a distribution of quantitative observations can be calculated using the following formula:

$$\text{Estimated Skew} = \frac{1}{n} \sum_{i=1}^n \left(\frac{x_i - \bar{x}}{s} \right)^3$$

where $\bar{x}$ and s are the sample mean and standard deviation, respectively. Distributions that are fairly symmetric, such as those in **Fig. 5**, with sample mean approximately equal to the sample median, have values of skew equal or close to zero. Positively- or right-skewed unimodal distributions, such as **Fig. 6**, have values of skew greater than zero, where the sample mean is typically larger than the sample median (e.g., see **Table 3**). In contrast, negatively- or left-skewed unimodal distributions, such as Class 2's distribution of scores in **Fig. 4**, have values of skew less than zero, and the sample mean is typically smaller than the sample median (e.g., see **Table 2**). The magnitude of skew gives a measure of the amount of asymmetry in a data distribution, with larger values indicating more asymmetric distributions. When considering multimodal distributions that are skewed, such as Class 1's distribution of scores in **Fig. 4**, categorizations of skewness values, and the corresponding relationships between the sample mean and median, may differ from those that apply to unimodal distributions, so it is important to also visually explore these characteristics with graphs.

Fig. 6 Dot plot and corresponding box plot depicting a right- or positively-skewed distribution of students' midterm exam scores. Plots were made using "Explore Quantitative Data" from "The Art and Science of Learning From Data Web Apps" <https://artofstat.com/web-apps>.

Table 3 Descriptive statistics of students' midterm exam scores displayed in **Fig. 6**.

n	Mean	Standard deviation	Minimum	Q1	Median	Q3	Maximum	IQR	Skew
30	81.1	8.40	68.0	76.0	78.5	83.0	100.0	7.0	0.97

Kurtosis

When describing a data distribution's shape, we can also characterize how extreme its tails are to help identify potential issues with outlying or extreme observations. *Kurtosis* is a descriptive statistic used to help measure how data disperse between a distribution's center and tails, with larger values indicating a data distribution may have "heavy" tails that are thickly concentrated with observations or that are long with extreme observations. A distribution's kurtosis can be calculated using different formulas, including the following:

$$\text{Estimated Kurtosis} = \frac{1}{n} \sum_{i=1}^n \left(\frac{x_i - \bar{x}}{s} \right)^4$$

Because the standardized distance each value falls from the mean is raised to the fourth power, kurtosis increases for every observation that differs from the mean but is most impacted by observations that are more than one standard deviation above or below the mean and lie in a data distribution's tails. For example, the normal distribution, which is a unimodal, bell-shaped distribution that looks similar to the data distribution on the left in Fig. 5, has kurtosis equal to three, where most of the distribution is concentrated around the mean and its tails quickly approach zero in height. Because the normal distribution often serves as a reference distribution for comparing other distributions, the value of a distribution's kurtosis is typically reported as the difference between its kurtosis and the kurtosis of the normal distribution, or as its "excess kurtosis." Data distributions with positive values of excess kurtosis, such as Class 2's distribution of midterm exam scores (Fig. 4), tend to have heavier tails than the normal distribution, whereas those with negative values of excess kurtosis, such as the approximately uniform data distribution shown in Fig. 5, tend to be broader distributions with few to no extreme observations. In general, higher positive values of excess kurtosis suggest that there may be issues with outliers in the data, offering additional information about the data's distribution that should be explored further by checking the data's accuracy and summarizing it graphically.

Measures of location

In addition to collectively summarizing a variable's data distribution, we often want to describe a single value or data point in relation to the full set of values. This may be because we want to quantify how far it is from the center of the data, or because we wish to communicate something about that data point, such as how a single test score compares to the whole group of test takers. There are two common approaches to describing location. The location of a data point can be reported as a *percentile*, stating the proportion of the data at or below the selected value. We could also report a *standardized score* to describe how the observation lies in relation to the mean, above or below, using the standard deviation as our measuring stick.

Percentiles are commonly used to report standardized test scores to students and parents. Typically, in this context, percentiles are defined to be the proportion of the test scores that are less than but not equal to the selected score, expressed as a percentage. This definition excludes the possibility of a 100th percentile, since each value is included in the set and cannot be less than itself. However, percentiles can be defined in other ways, so it is important for writers to include the definition they are applying. In all uses, percentiles divide the data into 100 slices and use these cuts as measures of location. Other -iles can be used, such as quartiles, quintiles, and deciles, which divide the data into four, five, or ten slices, respectively. These slices each contain approximately the same number of data points but are often unequal in length. For example, test scores falling in the first decile may range from 0 to 46 and those falling in the second decile may range from 47 to 52, but each decile still contains the same number (10%) of test scores. The median is defined as the 50th percentile.

Standardized scores are most often used with a symmetric unimodal data distribution and are found by subtracting the mean from the value of interest and dividing the difference by the standard deviation:

$$\text{Standardized Score} = \frac{x - \bar{x}}{s}$$

This standardized value tells us how many standard deviations above or below the mean a data point falls. Standardized scores are typically used to gauge a point's extremeness, or to compare values from multiple variables with different scales. The process of calculating a standardized score is an example of standardization, and similar calculations are used in finding scale scores on large-scale high-stakes testing. When data are approximately normally distributed, common rules of thumb can be developed and used. For example, values that are greater than three standard deviations away from the mean ($|\text{standardized score}| \geq 3$) would be unusual in a normal distribution. Although such rules only apply to normally distributed data, standardized scores can be calculated for any data.

Describing multivariate data

Although this entry primarily focuses on summarizing univariate data, data sets often contain data on multiple variables, not just one, that may be related. Statistics that describe *multivariate data*, that is, data collected on two or more variables for each observational unit, help us summarize and explore potential relationships between variables that may not be evident when summarizing each variable individually. For instance, the previously described data set on high school students contains multivariate data because data were collected on multiple variables for each student, including their gender identity, year in school, GPA, and SAT score. With these multivariate data, we can describe each variable not only individually, but also in relation to the other variables

to help uncover and understand different relationships, such as the relationship between a student's GPA and SAT score and the relationship between a student's year in school and SAT score.

When summarizing multivariate data, we first describe each variable individually, using descriptive statistics such as those discussed in previous sections. After exploring each variable of interest individually, we then numerically and graphically summarize them together to explore their potential relationship(s). Similar to univariate data, the number and types of variables we want to simultaneously summarize determines which types of descriptive statistics we can use and the types of analyses we can perform. "In this entry, we focus on graphical and numerical summaries used to describe the relationship between two numerical variables, that is, *bivariate numerical data*, but descriptive statistics and analyses also exist for other types of multivariate data, including the combination of numerical and categorical variables."

Describing bivariate numerical data

We use scatterplots to visualize and identify patterns and trends in bivariate numerical data. In a scatterplot, each observation is represented by a point or dot whose position on the horizontal and vertical axes indicates its value for each respective variable. Plotting each observation in a scatterplot and identifying patterns among the points can help us determine if a relationship exists between two numerical variables.

Often, we use scatterplots to assess the linear relationship between two numerical variables. Scatterplots might show positive linear trends, negative linear trends, or no linear trend at all. A scatterplot shows a positive linear trend if the variable on the vertical or y-axis tends to increase at a constant rate as the variable on the horizontal or x-axis increases. Conversely, if the variable on the y-axis tends to decrease at a constant rate as the variable on the x-axis increases, then the scatterplot shows a negative linear trend.

The *correlation coefficient*, r , is a statistic for measuring the strength and direction of a bivariate linear relationship and is calculated using the following formula:

$$r = \frac{\sum_{i=1}^n (x_i - \bar{x})(y_i - \bar{y})}{\sqrt{\sum_{i=1}^n (x_i - \bar{x})^2 \sum_{i=1}^n (y_i - \bar{y})^2}}$$

The correlation coefficient can assume any value between -1 and 1 ($-1 \leq r \leq 1$), where its sign indicates the direction of the linear trend and its magnitude indicates the strength of the linear relationship between the two numerical variables. For example, the correlation coefficient for a perfect positive linear relationship where all observations lie in a straight, positive line is $r = 1$, whereas the correlation coefficient for a perfect negative linear relationship is $r = -1$. The weaker the linear relationship tends to be, the closer in magnitude the correlation coefficient is to 0. Because the correlation coefficient is easily affected by influential observations and may not accurately reflect the true pattern in the data, it is important to also look at the corresponding scatterplot when describing the relationship between two numerical variables. For example, if the correlation coefficient is close to or approximately 0, looking at the scatterplot will determine whether there is no relationship between the two variables or if the relationship is simply not linear.

Example

Descriptive statistics are reported and used in educational reports and research. For example, [Table 4](#) presents several different statistics that summarize 2016–2017 United States high school seniors' most recent SAT scores for each state in the South Census Region ([United States Census Bureau, 2013](#)) and the entire United States ([Snyder et al., 2019](#)). To obtain each state's reported means ("Mean score") and standard deviations ("SD"), along with its "percentage distribution of seniors who had taken the SAT, by total SAT score range," the original data set would have contained multiple numerical variables for each student, including their total, evidence-based reading and writing, and math SAT scores, as well as one categorical variable, their state. To obtain the percent of graduating high school seniors in 2017 who took the SAT for each state, another data set would have contained each state's total number of graduating high school seniors in 2017, as well as the number of those seniors who took the SAT.

The descriptive statistics reported in [Table 4](#) summarize the center, variability, and shape of each state's distribution of total SAT scores. For example, the United States' mean and standard deviation for total SAT scores indicate that, on average, 2016–2017 United States high school seniors who took the SAT earned a total SAT score of 1060 points, and scores tended to vary from that mean by 195 points on average. In South Carolina, 2016–2017 high school seniors who took the SAT had a mean total SAT score similar to the national mean, at 1064 points, but their total SAT scores varied less from their mean on average ($SD = 174$) than those in the United States did ($SD = 195$). In contrast, the mean total SAT score for those in the District of Columbia, at 950 points, was lower than the national average, but students' scores were more variable, varying an average of 240 points from the mean. Across the states in the South Census Region, the mean total SAT scores form a bimodal distribution, with eight of the states having mean total SAT scores between 1000 and 1100 points, and four of the states having mean total SAT scores between 1200 and 1250 points (see [Fig. 7](#)). The variability among 2016–2017 seniors' SAT total scores was also different across the South Census Region states, with scores in West Virginia ($SD = 171$), South Carolina ($SD = 174$), North Carolina ($SD = 176$), and Georgia ($SD = 177$) varying the least from each of their respective means on average and those in the District of Columbia ($SD = 240$) and Oklahoma ($SD = 257$) varying the most.

Each state's percentage distribution of total SAT scores for 2016–2017 high school seniors who took the SAT offers information about how students' scores were distributed across the range of possible scores from 400 to 1600 points. Visually summarizing these

Table 4 Table of Scholastic Aptitude Test (SAT) mean scores, Standard Deviations (SD), and score ranges for high school seniors who took the SAT in 2017, as well as the percentage of the 2017 graduating class of high school seniors who took the SAT by state in the South Census Region.

State (abbreviation)	Evidence-based reading and writing						Percentage distribution of seniors who had taken the SAT, by total SAT score range							Percent taking SAT

Fig. 7 Histogram of states' mean total SAT scores for 2016–2017 high school seniors in the South Census Region who took the SAT.

distributions with histograms (see Fig. 8) illustrates similarities and differences across the states' distributions, and the grayscale shading conveys the percentage of the state's 2017 graduating class of high school seniors who took the SAT. States with darker shadings, such as Delaware, Florida, and District of Columbia, had over 80% of their 2017 graduating classes take the SAT. However, when comparing these states' distributions of total SAT scores, we notice that Delaware's and Florida's percentage distributions are unimodal and fairly symmetric, whereas the District of Columbia's distribution of scores, while also unimodal, is right-skewed. In general, Delaware's and Florida's distributions of total SAT scores are similarly centered (Mean = 996 and 1017, respectively), variable (SD = 197 and 190, respectively), and shaped, with most of the students scoring between 800 and 1190 points. In contrast, the total SAT scores of 2016–2017 high school seniors in District of Columbia who took the SAT tended

Fig. 8 Histograms of total SAT scores for 2016–2017 United States high school seniors by state, where the shading represents the percentage of the state's graduating class of high school seniors in 2017 who took the SAT.

to be relatively lower on average (Mean = 950), with most lying between 600 and 990 points, and a few higher than that, creating a right-skewed distribution with greater variability ($SD = 240$). Across all the distributions, there are noticeable similarities and differences in how total SAT scores were distributed, not just in mean and variability, but also in shape. Most of the South Census Region states' distributions of total SAT scores are unimodal and fairly symmetric (e.g., DE, FL, MD, NC, SC, TX, and VA), but other distributions are unimodal and right skewed (e.g., DC and WV) or unimodal and left skewed (e.g., KY, MS, and TN). Further, the differences in shading illustrate how approximately half the states had less than 15% of their 2017 graduating classes take the SAT, whereas the other states had at least 49% take the exam.

Fig. 9 Scatterplot of each South Census Region state's mean total SAT score for 2016–2017 high school seniors by its percent of graduating class of high school seniors in 2017 who took the SAT.

The notable differences in the percent of the 2017 graduating class who took the SAT in each state and the bimodal distribution of the states' mean total SAT scores (see Fig. 7) suggest that there might be a relationship between these two numerical variables. Visualizing these variables in a scatterplot (see Fig. 9), we notice that there are two distinct groups of points—states in which less than 15% of their 2017 graduating classes took the SAT and states in which more than 45% took it. The scatterplot and correlation ($r = -0.84$) both suggest that there is a fairly strong, negative linear relationship between these two numerical variables for these South Census Region states; as the percent of the 2017 graduating class who took the exam increases, the mean total SAT score tends to decrease for these states. When exploring this relationship separately for each group, the correlations still suggest fairly strong, negative linear relationships ($r = -0.76$ and $r = -0.74$, respectively, for states with less than 15% and more than 45% of their 2017 graduating classes taking the SAT). These bivariate relationships suggest that the bimodal distribution of mean total SAT scores we discovered in Fig. 7 is at least partially explained by the percent of the 2017 graduating seniors in a South Census Region state who took the SAT, allowing us to uncover additional information beyond what was offered by the univariate summaries alone.

Conclusion

When dealing with data in any context, an important first step is to explore properties of the data using descriptive statistics. We have discussed how variables can be divided into two types, categorical and numerical, and what tools are appropriate for each type. For categorical variables, counts and relative frequencies are key and are often displayed using frequency tables and bar charts. For numerical variables, we seek to describe features of the variable's distribution including its center, variability, and shape, and how the location of individual observations relate to that distribution. By developing meaningful summary statistics about variables in a data set, descriptive statistics not only allow for their own interpretations, but also lay the groundwork for further analysis such as exploratory data analysis, statistical modeling, and statistical inference; for further reading, see Çetinkaya-Rundel and Hardin (2021). Using and interpreting descriptive statistics helps us move beyond complex lists of variables and values to make meaningful observations about the population of interest and the variables measured.

Correlations and associations

Introduction

It can be argued that correlations are the first statistical concept that most individuals learn, albeit perhaps unbeknownst at the time. From a very young age, children learn about, and through, relationships, and they continue to learn through relationships as they develop (e.g., consequences that may result from good or poor behaviors). In the statistical world, correlations are arguably the foundation of basic as well as advanced statistics given that relationships are either implicit or explicit in these statistics (Chen and Popovich, 2011).

Correlation coefficients are the statistics that allow us to describe relationships in terms of strength and direction. Correlation coefficients generally range in absolute value from 0 to 1, with statistics closer to an absolute value of 1 reflecting stronger relationships. Directionality can be assessed by the sign of the correlation. Positive correlations suggest that values that increase on one variable also increase on the second variable. Negative correlations suggest that values that increase on one variable decrease on the second variable. Correlations at or near zero suggest little or no relationship; in other words, there is no discernible pattern to the relationship between variables.

Correlations have many applications and can be used as descriptives statistics or inferential statistics. This article will focus on bivariate (i.e., two variables) parametric and non-parametric correlation indexes as well as characteristics of correlations, and will begin with a concise history of correlations.

History of correlations

Karl Pearson, the scholar for whom the Pearson product moment correlation is named, is considered by many to be the founder of scientific statistics (Eves, 2002) and the first modern statistician (Yasmin, 2007). Pearson (1887–1936) was a scientist in England and directed the University of London's Francis Galton Laboratory for National Eugenics (Eves, 2002). Pearson's work was

influenced by Sir Francis Galton (1822–1911) (Yasmin, 2007; Blyth, 1994), the scientist and cousin of Charles Darwin who created new statistical methods for studying heredity (Eves, 2002), including correlation and regression (Blyth, 1994).

Within the history of statistics, the discovery of correlation and regression is regarded as one of the most important developments (Fienberg, 1992; Stigler, 1986). Pearson credited Galton for the creation of correlation, noting no preceding work by Gauss or Bravais. Pearson also recognized that Galton himself realized the unprecedented discovery with which he had made (Pearson, 1920). As noted by Pearson (Pearson, 1920):

If you think Galton did not appreciate the width of his new methods, you must turn to the last paragraph of his *Introduction to the Natural Inheritance*.

The conclusions cannot, however, be intelligibly presented in an introductory article. They depend on ideas that must first be well comprehended, and which are now novel to the large majority of readers and unfamiliar to all. But those who care to brace themselves to a sustained effort, need not feel much regret that the road to be travelled over is indirect, and does not admit of being mapped beforehand in a way they can clearly understand. It is full of interest of its own. It familiarizes us with the measurement of variability, and with curious laws of chance that apply to a vast diversity of social subjects. This part of the inquiry may be said to run along a road on a high level that affords wide views in unexpected directions, and from which easy descents may be made to totally different goals to those we have now to reach. I have a great subject to write upon

Galton (1889).

According to Pearson (Pearson, 1920), it was Galton's book (Galton, 1889) that enticed Pearson, along with two other scholars (Walter F. R. Weldon and Francis Y. Edgeworth) to study correlation. Weldon applied correlation to study organs in shrimps and other species, while Edgeworth applied the methods to moral or social sciences (Stephen, 1978). Interestingly, Galton termed the statistic the "index of co-relation" (Galton, 1889), Weldon termed it "Galton's function", and Edgeworth replaced both these terms with "coefficient of correlation" (Pearson, 1920), the latter term of which has seemed to stand the test of time.

Although Galton is credited for introducing correlations in 1888, Pearson is credited for refining many of the ideas introduced by Galton (Blyth, 1994). Pearson's student, G. U. Yule, found that if the regression was linear, the regression slope was still found to be $\frac{\rho\sigma_Y}{\sigma_X}$ (Blyth, 1994), where the correlation coefficient ρ is the regression slope when both variables were scaled by their standard deviations, σ_Y is the standard deviation of Y , and σ_X is the standard deviation of X . Thus, by the early 1900s, the application of regression and correlation to the linear model had been made (Blyth, 1994). Pearson realized the need, and worked on albeit unsuccessfully, generalizing the correlation to nonlinear models (Pearson, 1920). Much of the continued development of the correlation coefficient after this time is the result of Sir Ronald Aylmer Fisher, including calculating the sampling distribution of an estimate of the correlation coefficient (Fisher, 1915) and demonstrating the value of the correlation in clarifying aspects of heredity and genetics (Fisher, 1918).

The history of correlations is quite interesting and not without controversy (e.g., Norton and Pearson, 1976). Readers interested in learning more are directed to the references cited within as what is presented here is but a small snippet of the historical underpinnings.

Types of bivariate correlations

There are a number of different types of bivariate correlation indexes (i.e., correlation coefficients computed for two variables). As we will see, most were developed to overcome limitations with the Pearson correlation, the correlation with which we will begin the discussion. Likely the most common correlation coefficient, the Pearson correlation coefficient is a parametric correlation coefficient.

Parametric correlations

Fisher formulated the framework for parametric statistical inference (Fisher, 1922) (see Hald, 2007, for a detailed account of the history of parametric statistics during this time). However, it was not until Wolfowitz (1942) that the term *parametric* was coined, as he distinguished parametric from nonparametric functional forms. Parametric statistics are those for which the variables used within the statistical procedure have a functional form that is known. In other words, parametric statistics are those statistical procedures that assume the data, which is sampled from the population, can be sufficiently modeled by a probability distribution with a parameter set that is fixed (Geisser, 2006). The normal distribution is the most common distributional assumption for parametric procedures. Within the umbrella of correlations, there exist both parametric and non-parametric (i.e., distribution-free) correlations.

Pearson product moment correlation

The Pearson product moment correlation (hereinafter referred to as Pearson), as noted previously, is credited in large part to Karl Pearson's work proceeding Galton. The Pearson correlation, also referred to as the Galton-Pearson correction (Blyth, 1994), is arguably the most utilized correlation coefficient, and there is some research to support this. For example, a review of more than 18,000 psychology articles published in 2014 found that an effect size measure of some type was reported in about 25% of the publications

(de Winter et al., 2016). Of correlations reported, Pearson was reported about twice as often as Spearman's rho (discussed in a later section) (de Winter et al., 2016).

The Pearson correlation is most appropriate to compute when both variables are at least interval in measurement scale and when there is a linear (as compared to non-linear) relationship between those variables (specifically, a linear relationship between X and Y , in other words, a bivariate normal distribution, is assumed for the Pearson), although there are special cases of the Pearson when this is not the case. (A variable that is interval in measurement scale is one where the units can be ordered and equal differences between the values imply equal distance in terms of the characteristic being measured (Hahs-Vaughn and Lomax, 2020a)) An initial understanding of covariance is required, prior to the introduction of correlation.

Covariance

The variance and correlation share commonalities in that the correlation is simply the standardized covariance. The population covariance is denoted by σ_{XY} and calculated as follows:

$$\sigma_{XY} = \frac{\sum_{i=1}^N (X_i - \mu_X)(Y_i - \mu_Y)}{N}$$

where X_i and Y_i are the scores for case i on variables X and Y , respectively, and μ_X and μ_Y are the population means for variables X and Y , respectively. N represents the population size.

The sample covariance, s_{XY} , is computed as follows:

$$s_{XY} = \frac{\sum_{i=1}^n (X_i - \bar{X})(Y_i - \bar{Y})}{n - 1}$$

where $\bar{X}$ and $\bar{Y}$ are the sample means for variables X and Y , respectively, and n is the sample size. The denominator of $n-1$ is the correction necessary to obtain an unbiased estimate of the population parameter.

The formula for the covariance is essentially an average of the product of the paired deviation scores. When variables X and Y are positively related, then the deviation scores will tend to be of the same sign, their products will tend to be positive, and the covariance will be a positive value (i.e., $\sigma_{XY} > 0$). When variables X and Y are negatively related, then the deviation scores will tend to be of opposite signs, their products will tend to be negative, and the covariance will be a negative value (i.e., $\sigma_{XY} < 0$). Finally, in the case of unrelated variables X and Y , then the deviation scores will consist of both the same and opposite signs, their products will be both positive and negative and sum to zero, and the covariance will be zero (i.e., $\sigma_{XY} = 0$).

A computational formula for the population covariance, which is less wieldy than the previously provided formula, is as follows:

$$\sigma_{XY} = \frac{N \left(\sum_{i=1}^N X_i Y_i \right) - \left(\sum_{i=1}^N X_i \right) \left(\sum_{i=1}^N Y_i \right)}{N^2}$$

where the first summation involves the cross-product of X multiplied by Y for each case summed across all N cases, and the other terms should be familiar.

The corresponding computational formula for the sample covariance is as follows:

$$s_{XY} = \frac{n \left(\sum_{i=1}^n X_i Y_i \right) - \left(\sum_{i=1}^n X_i \right) \left(\sum_{i=1}^n Y_i \right)}{n(n - 1)}$$

where the denominator is $n(n-1)$ so as to yield an unbiased sample estimate of the population covariance.

The covariance serves a useful purpose in many contexts, but the interpretation can be challenging as the magnitude of a covariance can take on any value. This results in further difficulty in making comparisons between covariance values. A large covariance may reflect a strong relationship, but it may also simply be an artifact of the metric of the variables. Correlation coefficients, which are standardized covariance values (as noted earlier), measure the relationship between variables and are easier to interpret than covariances.
